Three rice paddy fields under farmers' actual management conditions were investigated from May to April at Bibai (43°18'N, 141°44'E), in central Hokkaido, Japan to evaluate the carbon (C) sequestration and contribution of CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O fluxes to a global warming potential (GWP). CH<sub>4</sub> and N<sub>2</sub>O fluxes were measured by placing the chamber over the rice plants covering four hills and CO<sub>2</sub> fluxes from rice plants root free space in paddy fields were taken as an indicator of soil microbial respiration (R<sub>m</sub>) using the closed chamber method. Annual cumulative R<sub>m</sub> ranged from 422 to 519 g C m<sup>-2</sup> yr<sup>-1</sup>; which accounted for 54.7 to 55.5 % mainly during the rice growing season. Annual cumulative CH<sub>4</sub> emission ranged from 75.5 to 116 g C m<sup>-2</sup> yr<sup>-1</sup> and this contribution occurred entirely during the rice growing period. Annual cumulative N<sub>2</sub>O emission ranged from 0.091 to 0.154 g N m<sup>-2</sup> yr<sup>-1</sup> and 73.5 to 81.3% of the positive annual N<sub>2</sub>O emission observed during the winter-fallow season. Soil C sequestration was estimated as the difference between net primary production (NPP) and C loss through R<sub>m</sub>, CH<sub>4</sub> emission and crop C harvest. The soil C sequestration ranged from -305 to -365 g C m<sup>-2</sup> yr<sup>-1</sup>, indicating that the C loss could not be compensated for by C input through NPP. Carbon loss was much higher (62 to 66%) in winter-fallow season than growing season. The annual net GWP from the investigated paddy fields ranged from 3823 to 5016 g CO<sub>2</sub> equivalent m<sup>-2</sup> yr<sup>-1</sup>. Annual GWP<sub>CH<sub>4</sub></sub> accounted for 71.9 to 86.1% of the annual net GWP predominantly from the rice growing period. These results indicate that CH<sub>4</sub> dominated the rice paddy's net GWP.

**Key words:** Carbon sequestration; methane; carbon dioxide; nitrous oxide; global warming potential; paddy field.

## 1 **1. Introduction**

2 Rising atmospheric levels of the greenhouse gases (GHGs) like carbon dioxide (CO<sub>2</sub>), methane  
3 (CH<sub>4</sub>), and nitrous oxide (N<sub>2</sub>O) have caused an increase in radiative forcing of the earth's  
4 atmosphere. Agriculture plays an important role in the global flux of these gases [1]. Rice  
5 paddies in monsoonal Asia have an important role in the global budget of GHGs [2], but there  
6 is still considerable uncertainty in the magnitude of the net fluxes from these ecosystems.  
7 Many of the factors controlling gas exchange between rice paddies and the atmosphere are  
8 different from those in dryland agriculture and other ecosystems because rice is flooded during  
9 most of its cultivation period [2]. Any change in either management or climate/soil conditions  
10 will alter the biochemical or geochemical processes, which finally leads to changes in the gas  
11 fluxes [3]. For example, incorporating crop straws into soil can increase carbon (C)  
12 sequestration [4] but elevate CH<sub>4</sub> fluxes [5]. Lower CH<sub>4</sub> fluxes due to water drainage may  
13 increase N<sub>2</sub>O fluxes [6]. Studies have shown that a large amount of GHGs are released from  
14 paddy fields and that a substantial quantity of CO<sub>2</sub> is sequestered by plants in paddy fields.  
15 These two processes help to regulate GHGs in rice paddy ecosystems [7]. Since each GHG has  
16 its own radiative potential [8], the estimation of net global warming potential (GWP) in a crop  
17 production system must account for all of the three gas constituents [3].

18  
19 Net exchanges of CO<sub>2</sub> and CH<sub>4</sub> between rice paddies and the atmosphere are controlled by  
20 several biological and physical processes. CO<sub>2</sub> exchange in rice paddies is driven by  
21 photosynthesis and autotrophic (plant) and heterotrophic (mainly microbial) respiration [9].  
22 Plant photosynthesis leads to uptake of CO<sub>2</sub> from both the atmosphere and from respired CO<sub>2</sub>  
23 emitted by the soil and floodwater. CH<sub>4</sub> is released to the atmosphere by ebullition, diffusion

1 and by transport through rice plant aerenchyma tissue [10]. More than 90% of the total CH<sub>4</sub>  
2 emission occurs through the aerenchyma system of the rice plants [11]. For that reason most  
3 estimates of gas fluxes in paddy fields have used chambers placed over plants, during  
4 measurement [2]. Previous studies considered CH<sub>4</sub> and N<sub>2</sub>O but not CO<sub>2</sub> when estimating  
5 GWP in paddy fields, because both respiration and photosynthesis activities contributed to CO<sub>2</sub>  
6 concentration change in the chamber [12]. There has been a great deal of information to  
7 improve our understanding of the processes of C cycle and C storage in soils. This has arisen  
8 because of the need to sequester C to overcome global climate change [13]. Carbon  
9 sequestration is the process of transferring CO<sub>2</sub> from the atmosphere into the soil through crop  
10 residues and other organic solids in a form that is not immediately reemitted. In keeping with  
11 definitions suggested by the Intergovernmental Panel on Climate Change [14], sequestration is  
12 an increase in the C stock of a pool other than the atmosphere. In attempts to quantify the C  
13 sequestration in paddy ecosystems that would accompany changes in agricultural practices, the  
14 change in C emissions associated with management practices has largely been overlooked. The  
15 GWP of CH<sub>4</sub> and N<sub>2</sub>O emissions from paddy soils had been estimated together or separately by  
16 numerous researchers [6,15,16]. With regard to the integrated greenhouse effect in CO<sub>2</sub>-  
17 equivalent of three gases (CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O), the available data are rather scarce. Therefore,  
18 the integrated GHG effect under various management practices and the status of “source” and  
19 “sink” of paddy fields are essential. Moreover, information regarding annual GHG fluxes and  
20 contribution of each GHG to the total GWP from rice growing and fallow periods is  
21 insufficient. Furthermore, because actual status of GHG emissions in regional agriculture is  
22 quite unclear, methodological research for increasing accuracy of estimations is required. In  
23 this study, we present the method of measurements of soil microbial respiration (R<sub>m</sub>) from

1 paddy fields. Thus, we have carried out one of the first field-level investigations in paddy field  
2 to estimate C sequestration using  $R_m$ , direct measured from paddy field. Therefore, the  
3 objective of the present studies to estimates the C sequestration in paddy fields and evaluates  
4 the contribution of  $CO_2$ ,  $CH_4$  and  $N_2O$  fluxes to GWP.

## 6 **2. Materials and methods**

### 7 *2.1. Site description and field management schemes*

8 Field investigations were carried out from late May to April at Kita-mura ( $43^{\circ}18'N$ ,  $141^{\circ}44'E$ )  
9 near Bibai, located in Central Hokkaido, a major rice-growing area of Japan. We investigated 3  
10 rice paddy fields under farmers' actual management conditions. Three fields of  $D_1$ -M  
11 (drainage-multiple),  $D_2$ -M (drainage-multiple) and  $D_3$ -S (drainage-single) were mineral soil  
12 dressed peat. Hokkaido is the most recently developed land in Japan. Since its development in  
13 the Meiji Era (1867-1911), many of the peatlands in Hokkaido, Japan, were reclaimed as  
14 paddies or dry fields [17]. In central Hokkaido, peatland are distributed mainly in the lowlands  
15 along the main river, Ishikari. Especially after the year 1945, most of the Ishikari peatlands  
16 have been used for paddy cultivation according to the systematic development plan of the  
17 Japanese Government. In the 1960s, the peat soils (studied area) were drained, top dressed with  
18 about 30 cm of mineral soil, and turned into productive crop fields [18]. The mineral soil  
19 (dressing) thickness of soil-dressed peatland fields of  $D_1$ -M,  $D_2$ -M and  $D_3$ -S were  $20 \pm 4.2$ ,  
20  $29 \pm 5.4$  and  $29 \pm 5.4$  cm, respectively. All of the fields under single cropping  $yr^{-1}$  and a paddy-  
21 fallow-paddy crop rotation as system. Before the experiment, paddy rice had been cultivated in  
22 all the fields for approximately consecutive 10 years. The prevailing local practice for rice  
23 straw management is to leave rice straw on paddy fields after harvest in autumn and to

1 incorporate the straw into the soil in the following spring (early May) by plowing. The study  
2 area has a cold climate with a long period of snow cover in winter. During the winter-fallow  
3 period (October to April), between harvest and the next year's planting, the rice straw was left  
4 on the unplowed fields. From November to April, crop residues were covered by deep snow  
5 with subfreezing air temperatures. We observed that a variable amount of rice straw leftover on  
6 the fields resulted from different yields of the previous year's paddy rice crops; farmers  
7 collected only grain and combine harvesters left short pieces of rice straw on the soil surface as  
8 spreading on fallow fields. In central Hokkaido, as we mentioned above, the kind and  
9 abundance of leftover organic materials was mainly from rice plants, no other weeds or/if any  
10 it was very small and negligible. In winter-fallow period, the duration between the rice harvest  
11 in autumn (end of September) and the first snowfall was about 45 days. This short duration and  
12 gradually decreasing air temperature is not favorable for weed growth. Furthermore, the fields  
13 remain under deep snow cover until the next spring (first week of April). The selected fields  
14 included different water management practices. Multiple drainage (frequency of drainage, two  
15 times) was done in D<sub>1</sub>-M and D<sub>2</sub>-M, and single drainage (mid-season) in middle of growing  
16 season was done in D<sub>3</sub>-S field. The duration of each drainage was 10 days. All fields were  
17 finally drained for harvest at the end of the growing season. The difference in water  
18 management practices among the fields might have governed mainly due to differences in  
19 amounts of leftover rice residues and soil condition. Drainage practices were commonly  
20 selected to avoid strong reductive conditions and to promote the decomposition of leftover rice  
21 straw. Paddy field D<sub>3</sub>-S practiced single drainage even though this field received the highest  
22 amount of previous crop residues. However, the frequency of drainage depends on field  
23 conditions. Some physical and chemical properties of the investigated field's soils are

1 presented in [Table 1](#). Detailed information on amount of leftover straw on fields and other  
2 management practices are presented in [Table 2](#).

3

## 4 **2.2. Experimental layout and approach**

5 Three rice-paddy fields were selected under farmers' actual management conditions.  
6 Each field was used as treatment, and had three measurement positions. Field D<sub>1</sub>-M, D<sub>2</sub>-  
7 M and D<sub>3</sub>-S received different amounts of leftover rice straw from previous year's rice  
8 crop. We considered three treatments and three chambers per field, i.e., three treatments  
9 (three fields) and three replications (three chambers per field). The distance between each  
10 of the field sites was about 500–1000 m. Three chambers (three replicates) were placed in  
11 each field at an equal distance of 30 m. Immediately after transplantation, an aluminum  
12 chamber base of 61 cm × 31 cm × 7 cm (length × width × height), which has 1 cm × 2.5  
13 cm (width × deep) water groove on inner side, was installed in the waterlogged soil. The  
14 base groove was filled with water if the field-water table dropped below the groove level.  
15 To avoid soil disturbance during gas collection, boardwalks were constructed from border  
16 dikes across each sampling site. During the cropping period, all observations were made  
17 from the boardwalks to avoid disturbing the soil.

18

## 19 **2.3. CH<sub>4</sub> and N<sub>2</sub>O gas sample collection and analysis**

20

21 A closed-chamber method [5] was used to collect gas from the experimental fields.  
22 Transparent, rectangular gas-sampling chambers of 60 cm × 30 cm × 100 cm (length ×  
23 width × height) were constructed using 5-mm-thick acrylic sheets and placed on base  
24 over the rice plants covering four hills in the paddy fields. To prevent pressure gradients

1 between the interior and exterior of the chambers during flux measurement and gas  
2 sampling, a plastic lightweight bag was affixed inside. To measure the inside  
3 temperature, a digital electronic thermometer was attached inside the chamber with a  
4 silicon cork. A silicon tube with a three-way stopcock was also attached to each chamber  
5 with a silicon cork for gas sampling. Every sampling event was replicated three times.  
6 Sampling was carried out three to four times per month within 10:00 h to 15:00 h on each  
7 sampling day. The same approach was used at each field site on each sampling date. At  
8 each sampling time, gas was sampled at 0, 10, and 20 min using a 25-mL polypropylene  
9 syringe and was transferred into a 20-mL vacuum vial with a hypodermic needle. CH<sub>4</sub>  
10 concentrations of the collected gas samples were analyzed in the laboratory by a gas  
11 chromatograph equipped with a hydrogen flame-ionized detector (FID, SHIMADZU GC-  
12 8A, Shimadzu Corporation, Kyoto, Japan) while N<sub>2</sub> (flow rate: 100 kPa), H<sub>2</sub> (flow rate:  
13 50 kPa), and zero air (flow rate: 50 kPa) were used as the carrier, fuel, and supporting  
14 gas, respectively. Column and injector/detector temperature were set at 70 °C and 130  
15 °C, respectively. Cylinder for CH<sub>4</sub> standard of 2.0 and 10.0 ppmv, obtained from  
16 Hokkaido Air Water Inc, Sapporo, Japan, was used as the primary standard, and it had an  
17 injection volume of 1 mL. N<sub>2</sub>O concentrations were determined with a gas  
18 chromatograph equipped with a <sup>63</sup>Ni electron capture detector (ECD, SHIMADZU GC-  
19 14B, Shimadzu Corporation, Kyoto, Japan). N<sub>2</sub> was used as the carrier gas and the flow  
20 rate was maintained at 400 kPa. Column, injector, and detector temperatures were set at  
21 60, 250, and 340 °C, respectively. Calibration was performed using N<sub>2</sub>O standard gas at a  
22 concentration of 0.3 ppmv (Hokkaido Air Water Inc, Sapporo), and an injection volume  
23 of 1 ml.

#### 1 **2.4. Soil Microbial respiration ( $R_m$ ) measurement**

2 CO<sub>2</sub> fluxes were taken from rice plants root free space in paddy fields as an indicator of soil  
3 microbial respiration [19]. In general, distribution of rice roots in the subsurface soil below 20  
4 cm depth and the horizontal distribution of roots in 15 cm distance [20]. Immediately after  
5 transplantation, rice seedlings of 1-m<sup>2</sup> from three places of each field were plucked up. An  
6 aluminium chamber base of 31 cm × 31 cm × 7 cm (length × width × height), which has 1 cm  
7 × 2.5 cm (width × deep) water groove in inner side, placed in the middle of the rice plants root  
8 free space to set the chamber on them. The distance between the edge of chamber base and the  
9 rice plants was 69 cm in around. Therefore, the chamber base inside was free from rice roots.  
10 The base groove was filled with water to make the system air-tight when field was in drained  
11 condition. Transparent rectangular chambers of 30 cm × 30 cm × 60 cm (length × width ×  
12 height) made by 3-mm-thick acrylic sheets was used for  $R_m$  measurement in the paddy fields.  
13 Three chambers were placed in each field with equal distance (three replicates). Chamber was  
14 covered by dark sheet during  $R_m$  measurement. Every sampling event was replicated three  
15 times. Sample collection procedures and time were identical to gas sample collection for CH<sub>4</sub>  
16 and N<sub>2</sub>O but samples of air within the chamber were taken with a 50 mL polypropylene syringe  
17 at 0 and 6 minute after setting up chamber and transferred in to a 400 mL Tedlar<sup>®</sup> bag through  
18 a silicon tube attached to the top of the chamber.  $R_m$  (CO<sub>2</sub>) was analyzed within 2 h after  
19 collection with an infrared gas analyzer (FUJI ZFP-9, Fuji Electric Co., Ltd., Tokyo, Japan).

20

#### 21 **2.5. Gas flux calculation**

22

23 Gas fluxes were calculated from the linear increase or decrease of gas concentration in the  
24 chamber over time, using the following equation:

$$F (\text{mg C m}^{-2} \text{ h}^{-1}) = \rho \times V / A \times \Delta c / \Delta t \times 273 / T \times \alpha \quad (1)$$

where, F is the gas flux;  $\rho$  is the density of gas at the standard condition ( $R_m$  as  $\text{CO}_2 = 1.96 \times 10^6 \text{ mg m}^{-3}$ ,  $\text{CH}_4 = 0.716 \times 10^6 \text{ mg m}^{-3}$ , and  $\text{N}_2\text{O} = 1.97 \times 10^6 \text{ mg m}^{-3}$ ); V ( $\text{m}^3$ ) and A ( $\text{m}^2$ ) are the volume and bottom area of the chamber, respectively;  $\Delta c / \Delta t$  ( $\text{m}^3 \text{ m}^{-3} \text{ h}^{-1}$ ) is the gas concentration change in the chamber during a given period; T is the absolute temperature (K); and  $\alpha$  is the conversion factor for gas ( $\text{CO}_2 = 12/44$ ,  $\text{CH}_4 = 12/16$  and  $\text{N}_2\text{O} = 28/44$ ). A positive flux indicates the emission of gas from soil into the atmosphere, and a negative flux indicates its uptake from the atmosphere. The cumulative fluxes were calculated assuming the existence of linear changes in gas emissions between two successive sampling dates:

$$\text{Cumulative gas emission} = \sum_{i=1}^{n-1} (R_i \times D_i) \quad (2)$$

where,  $R_i$  is the mean gas flux ( $\text{mg m}^{-2} \text{ d}^{-1}$ ) of the two sampling times,  $D_i$  is the number of days in the sampling interval, and n is the number of sampling times. The cumulative gas flux of individual gases is 121 days for the rice growing season and it was 211 days for winter fallow season. Gas samples collections were not conducted during May due to land preparation and transplantation.

20

## 2.6. Soil and plant sample analysis

Initial soil samples (0-10 cm depth) were collected by hand using a stainless-steel auger and analyzed for chemical properties. Undisturbed 100  $\text{cm}^3$  soil cores and disturbed samples (PVC bag; about 500 g) were collected from the depths of 0-10 cm. Un-disturbed core samples were used to measure the bulk density. Bulk density  $\rho_b$  ( $\text{g cm}^{-3}$ ) was obtained by  $\rho_b = Ms/100$ , where Ms (g) is the mass of dry solids determined after drying the soil sample to constant weight at 105 °C in a 100  $\text{cm}^3$  core. Disturbed samples were air dried for more than 3 weeks in the

1 laboratory, and then passed through a 2-mm sieve to remove coarse materials. Soil texture was  
 2 determined by the pipette method. Soil pH was determined with a glass electrode pH meter  
 3 (HORIBA pH meter F-8, Horiba, Kyoto, Japan) in a supernatant suspension of 1:2.5 soil:water  
 4 mixture. To record the amounts of residues from the previous year's crop, rice straw for each  
 5 field was collected from three 1-m<sup>2</sup> quadrates and dried in an oven at 70°C for 3 days. Residue  
 6 was considered as the above ground harvested parts of rice plant, except grain. Dried soil and  
 7 plant samples from each field were ground (e.g., to powder) by hand with a mortar and pestle  
 8 to determine total C concentrations with a C–N analyzer (vario MAX CNS, Elementar  
 9 Analysensysteme GmbH, Langenselbold, Germany).

10

### 11 ***2.7. Net primary production (NPP) estimation***

12

13 Net primary production which includes above and below ground biomass of rice plant of the  
 14 investigated fields was estimated. Plant samples of three 1-m<sup>2</sup> quadrates from each field were  
 15 collected by hand immediately before the harvest [5]. Root sample was taken from the top 0-20  
 16 cm depth of soil. Aboveground samples were separated into grains, straw and stubble. Those  
 17 plant samples were dried and analyzed in the same way as described in the soil and plant  
 18 sample analysis.

19

### 20 ***2.8. Soil C sequestration (CS) estimation***

21 Soil C sequestration was estimated to correspond to the difference between NPP and C loss  
 22 through soil microbial respiration ( $R_m$ ), CH<sub>4</sub> emission and crop C harvest. CS (g C m<sup>-2</sup>) of each  
 23 field was estimated as follows (Fig. 1):

$$24 \quad CS_g = NPP - (R_m + CH_4 \text{ emission} + \text{grain harvest}) \text{ for rice growing period} \quad (3)$$

$$25 \quad CS_f = - (R_m + CH_4 \text{ emission} + \text{straw harvest}) \text{ for winter-fallow period} \quad (4)$$

1 For one year:

$$2 \quad CS_g + CS_f = NPP - (R_m + CH_4 \text{ emission} + \text{grain harvest} + \text{straw harvest}) \quad (5)$$

3 where  $CS_g$  and  $CS_f$  are the C sequestration during rice growing and winter-fallow period,  
4 respectively; Rice grain and straw yields of three 1-m<sup>2</sup> quadrates were investigated. Grain and  
5 straw carbon was calculated from dry weight and carbon content.

6

### 7 **2.9. Global warming potentials (GWP) estimation**

8 Global warming potential (GWP) is defined as the direct and indirect effects of cumulative  
9 radiative forcing integrated over a period of time from the emission of a unit mass of gas  
10 relative to some reference gas, CO<sub>2</sub> as the reference gas [21]. The GWP (g CO<sub>2</sub> equivalent m<sup>-2</sup>  
11 season<sup>-1</sup>) which is CO<sub>2</sub> based emission was computed from the GHG emissions of each field,  
12 using a 100-year time horizon, as recommended by IPCC [8] (conversion factors of 1 for CO<sub>2</sub>,  
13 28 for CH<sub>4</sub> and 265 for N<sub>2</sub>O). GWP was calculated as follows:

$$14 \quad \text{Net GWP} = \text{CO}_2 \text{ GWP} + \text{CH}_4 \text{ GWP} + \text{N}_2\text{O GWP} \quad (6)$$

15 Where,  $\text{CO}_2 \text{ GWP} = -(\text{CS} + \text{CH}_4) (\text{g CO}_2\text{-C m}^{-2} \text{ season}^{-1}) \times (44/12)$ ;

16  $\text{CH}_4 \text{ GWP} = \text{CH}_4 (\text{g CH}_4\text{-C m}^{-2} \text{ season}^{-1}) \times (16/12) \times 28$ ; and

17  $\text{N}_2\text{O GWP} = \text{N}_2\text{O} (\text{g N}_2\text{O-N m}^{-2} \text{ season}^{-1}) \times (44/28) \times 265$ .

18

### 19 **2.10. Statistical analysis**

20

21 Statistical differences were performed by Tukey's multiple comparisons test by using Excel

22 Statistics version 4.0 (Esumi Co. Ltd., Tokyo, Japan).

23

24

25

## 3. Results

### 3.1. Climatic conditions

Meteorological data during the rice growing and winter-fallow periods were recorded and presented in Fig. 2 a & b. During the rice-growing period (late May–September), the mean air temperature was 17.9°C (range: 12.9 to 21.1°C), which was 5.1°C lower than the average soil temperature at a depth of 3 cm. The total precipitation during rice-growing period was 611 mm, accounting for 48% of the annual total precipitation (1265 mm). The average air temperature after harvest to before the first snowfall (October–late November) was 8.2°C (range: 0.80 to 14.2°C). During the snowy period (late November–late April) the average air temperature was -2.2°C (range: -13.6 to 10.2°C) and snow depth averaged 58 cm (range: 0 to 120 cm). The mean annual temperature was 7.94°C, which was 0.8 °C higher than the 10-year average and the annual total precipitation was 87.5 mm higher than the 10-year average.

### 3.2. Greenhouse gas fluxes ( $R_m$ , $CH_4$ and $N_2O$ )

The cumulative  $R_m$  of the three paddy fields varied during the growing period (Table 3) and was ranged from 234 to 284 g C m<sup>-2</sup> growing season<sup>-1</sup>. The cumulative  $R_m$  during the rice growing season was 54.7 to 55.5% of the annual total  $R_m$ . The cumulative  $R_m$  (g C m<sup>-2</sup> season<sup>-1</sup>) of the three paddy fields, D<sub>1</sub>-M, D<sub>2</sub>-M and D<sub>3</sub>-S was ranged from 188 to 235 during winter-fallow period. The annual cumulative  $R_m$  of D<sub>2</sub>-M field showed the highest rate (519) and the lowest from D<sub>3</sub>-S D<sub>3</sub>-S (422) (Table 3). The CH<sub>4</sub> emission rate was much higher in rice growing period than winter-fallow and the contribution to the total annual emission was 100% from the rice growing period (Table 3). The cumulative CH<sub>4</sub> emission during rice growing season from paddy fields was ranged from 75.5 to 116 g C m<sup>-2</sup> ( This cumulative CH<sub>4</sub> emission data

1 was published in Naser et al., 2018, *Atmosphere*, 9, 212-MDPI). Non significant variation among the gas  
2 fluxes in growing season, whereas it was significantly differed ( $P < 0.01$ ) in winter-fallow  
3 season, even though the fluxes of  $\text{CH}_4$  during the winter-fallow period was very low or tended  
4 to be uptake. In winter-fallow, paddy fields  $\text{D}_2\text{-M}$  and  $\text{D}_3\text{-S}$  fields showed emission, on the  
5 other hand,  $\text{D}_1\text{-M}$  field showed uptake ( $-0.019 \text{ g C m}^{-2}$ ). The annual total  $\text{CH}_4$  emission showed  
6 similar trend as like as the growing period (Table 3). Very low  $\text{N}_2\text{O}$  flux was observed during  
7 the rice growing and winter-fallow period (Table 3) and they were varied significantly ( $P < 0.05$   
8 and  $P < 0.01$  for rice growing and winter-fallow period, respectively). The cumulative  $\text{N}_2\text{O}$   
9 fluxes ( $\text{g N m}^{-2} \text{ season}^{-1}$ ) of the three paddy fields during the rice growing period showed low  
10 emissions, which ranged from 0.003 to 0.036 and during the winter-fallow period showed low  
11 uptake as well as emissions, which ranged from -0.013 to 0.118. Annual basis  $\text{N}_2\text{O}$  flux ( $\text{g N}$   
12  $\text{m}^{-2} \text{ yr}^{-1}$ ) was highest in  $\text{D}_2\text{-M}$  (0.154) followed by  $\text{D}_1\text{-M}$  (0.091) and  $\text{D}_3\text{-S}$  (0.016) (Table 3).  
13 The  $\text{N}_2\text{O}$  emission rate was much higher in winter-fallow season than growing season and the  
14 contribution to the total annual emission was 73.5 to 81.3% from the winter-fallow season.

15

### 16 **3.3. Soil C sequestration (CS)**

17 The net primary production (NPP) at different paddy fields varied from 499 to 530  $\text{g C m}^{-2}$   
18 (Table 4). The NPP of  $\text{D}_1\text{-M}$  was lower (499  $\text{g C m}^{-2}$ ) than those of the other fields in this study  
19 and other two fields showed almost similar NPP 529 and 530  $\text{g C m}^{-2}$ . The amount of C  
20 harvested as grain ranged from 266  $\text{g C m}^{-2}$  to 298  $\text{g C m}^{-2}$ , accounting for 53 to 56% of the  
21 respective NPP. There was an irregular trend in amount of NPP and grain yield among the  
22 variables such as rice variety, inorganic N fertilizer addition, straw residue and water regime.  
23 And non significant relation was found with added inorganic N fertilizer or straw residue on

1 NPP and grain yield. We calculated one year C sequestration from paddy fields including  
2 growing and winter-fallow season (Table 5). The negative value of CS indicates C loss from  
3 the soil to the atmosphere. The losses of organic C through  $R_m$ ,  $CH_4$  emission and C harvested  
4 as grain exceeded the corresponding NPP values for all the paddy fields. As a result, soil C  
5 sequestration was negative (ranged, -305 to -365 g C m<sup>-2</sup> yr<sup>-1</sup>). During the rice growing and  
6 winter-fallow season all the fields showed net sources of C (Table 6). The status of C losses  
7 rather than C sequestration during winter-fallow period compared with growing period showed  
8 an increment in C losses from 62 to 92%. The negative C sequestration rate or C losses was  
9 much higher in winter-fallow season than growing season and the contribution to the annual C  
10 losses was 62% to 66% from the winter-fallow season.

11

#### 12 ***3.4. Combined climatic impact of CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O***

13

14 The calculated GWP values for all suites of GHGs are presented in Table 7. Positive GWP  
15 value indicated global warming and negative GWP value indicated mitigation. The  $GWP_{CO_2}$  of  
16 three drainage practiced fields showed positive GWP (ranged, 3.52 to 196 g CO<sub>2</sub> equivalent m<sup>-2</sup>  
17 <sup>2</sup> growing season<sup>-1</sup>). During winter-fallow season all fields acted as sources of  $GWP_{CO_2}$ . As a  
18 consequence, the  $GWP_{CO_2}$  varied from 689 to 861 g CO<sub>2</sub> equivalent m<sup>-2</sup> winter-fallow season<sup>-1</sup>.  
19 The  $GWP_{CO_2}$  emissions during winter-fallow period from D<sub>1</sub>-M, D<sub>2</sub>-M and D<sub>3</sub>-S fields were  
20 equivalent to 85, 81 and 99% of the annual  $GWP_{CO_2}$ , respectively.

21

22 The  $GWP_{CH_4}$  (g CO<sub>2</sub> equivalent m<sup>-2</sup> growing season<sup>-1</sup>) was higher in D<sub>3</sub>-S field (4312), this  
23 field received highest amount of rice residue (Table 7). D<sub>1</sub>-M and D<sub>2</sub>-M showed approximately  
24 34–35% lower  $GWP_{CH_4}$  emissions than single drainage field, D<sub>3</sub>-S.  $GWP_{CH_4}$  during winter-

1 fallow period was very low or tended to be uptake. In seasonal aspect,  $GWP_{CH_4}$  contributed  
2 100% to the annual  $GWP_{CH_4}$  mainly from the rice growing period.

3

4 The  $GWP_{N_2O}$  values of three drainage practiced fields D<sub>1</sub>-M, D<sub>2</sub>-M and D<sub>3</sub>-S during the rice  
5 growing period were 10.2, 15.1 and 1.36 g CO<sub>2</sub> equivalent m<sup>-2</sup>, respectively (Table 7). The  
6 value of  $GWP_{N_2O}$  from D<sub>1</sub>-M and D<sub>2</sub>-M fields was 8 and 11-fold, respectively, as high as that  
7 from single drainage practiced field (D<sub>3</sub>-S). The status of  $GWP_{N_2O}$  during winter-fallow season  
8 compared with growing season showed an increment in N losses from 171 to 284%. In  
9 seasonal aspect,  $GWP_{N_2O}$  contributed 73 to 79% to the annual  $GWP_{N_2O}$  from winter-fallow  
10 season.

11

12 The annual net GWP (g CO<sub>2</sub> equivalent m<sup>-2</sup> yr<sup>-1</sup>) from D<sub>1</sub>-M and D<sub>2</sub>-M fields showed  
13 comparable value of 3823 and 3990, respectively, on the other hand, 5016 from single  
14 drainage practiced field (D<sub>3</sub>-S) (Table 8). Therefore, relative to the D<sub>3</sub>-S field, the net  
15 annual GWP was 23.8% smaller for the D<sub>1</sub>-M and 20.4% smaller for the D<sub>2</sub>-M fields.

16 The net GWP (g CO<sub>2</sub> equivalent m<sup>-2</sup> season<sup>-1</sup>) values from three paddy fields ranged from  
17 2978 to 4317 from growing season and 699 to 911 from winter-fallow season. On the  
18 basis of seasonal net GWP, the contribution to the annual net GWP was 77 to 86% from  
19 the growing season.

20

## 21 **4. Discussion**

22

### 23 ***4.1. Soil C sequestration***

24 The C sequestration values in this study ranged from -305 to -365 g C m<sup>-2</sup> yr<sup>-1</sup>,  
25 indicating that C gained, resulting from NPP were not sufficient to offset C losses from

1 paddy soils by  $R_m$ ,  $CH_4$  emission and C harvested as grain (Table 6). Thus, these paddy-  
2 fallow ecosystems were net sources of atmospheric  $CO_2$ . Paustian *et al.* [22] reported that  
3 the net difference between the photosynthetically-fixed  $CO_2$  that enters the soil as plant  
4 residues and the  $CO_2$  that is emitted from decomposition is much smaller. This difference  
5 determines the net C balance of the ecosystem, i.e., whether it is a source or sink for  $CO_2$ .  
6 The  $CO_2$  fixed in plant biomass through photosynthesis can be stored in the soil as  
7 organic C by converting plant residue into soil organic matter after the residue is returned  
8 to the soil [23].

9  
10  
11 The differences in C sequestration between the three paddy fields in this study were related to  
12 the crop residue management and drainage practice [24]. Crop residues addition influence C  
13 sequestration in two ways: one, carbon storage is done due to the addition of rice straw to soil,  
14 on the other hand, methane emission is enhanced with rice straw addition. Moreover, rice straw  
15 residues enhance both  $R_m$  and  $CH_4$  emissions [25,5]. Drainage and flooding also affect the  
16 condition of organic matter decomposition (aerobic or anaerobic), resulting in the change of  
17 responsible microorganisms [26]. Rees *et al.* [27] reported that some management practices  
18 are likely to have a negative impact on C sequestration.

19  
20 Our estimated C sequestration values (ranged,  $-305$  to  $-365$  g C  $m^{-2}$   $yr^{-1}$ ) were larger than the  
21 Hu *et al.* [28] estimated C sequestration values ( $-147$  to  $-222$  g C  $m^{-2}$   $yr^{-1}$ ) from onion-fallow  
22 field in Mikasa, central Hokkaido, Japan. Moreover, the values of C sequestration in this study  
23 were also higher than the reported C sequestration from grassland, onion, soybean, wheat and  
24 maize fields in Mikasa were  $-235$ ,  $-348$ ,  $-287$ ,  $-255$  and  $-227$  g C  $m^{-2}$   $period^{-1}$  (late March to  
25 mid December), respectively [29]. The result obtained by Koizumi *et al.* [30] in Japan  
26 indicated that the C sequestration value in upland rice and barley cropping ecosystems, in

1 peanut and wheat cropping ecosystems, and dentcorn and Italian ryegrass cropping ecosystems  
2 were  $-378$ ,  $-416$  and  $-630$  g C m<sup>-2</sup> yr<sup>-1</sup>, respectively. Koizumi [31] also reported that C  
3 budgets were different between the single-and double-cropping systems. The annual C balance  
4 was estimated to be  $-270$ ~ $-320$  g C m<sup>-2</sup> for the upland single-cropping fields (Upland rice, corn,  
5 peanut), and  $-160$ ~ $-270$  gC m<sup>-2</sup> for the upland double-cropping fields (Upland rice-barley, corn-  
6 barley, peanut-wheat) in Tsukuba, Japan. In this study, paddy fields during the rice growing  
7 season indicating C losses from soil. Our results contrast with the findings of Liping & Erda  
8 [32], they reported that, paddy soils store more C or avoid the C emission than the upland soils.  
9 In addition, Xiao *et al.* [7] reported that, rice paddy ecosystems may function as a significant  
10 CO<sub>2</sub> sink during the growing season. Paddy fields have been generally managed intensively for  
11 the better yield of rice, and many of the field management closely relate to the C cycling in the  
12 paddy ecosystem [26].

13

14 This study shown that different types of management can contribute at different rates of  
15 C losses from soil. Similar result also observed by Rees *et al.* [27]. Sainju *et al.* [23]  
16 reported that management practices can increase CO<sub>2</sub> emission from the soil by  
17 disrupting soil aggregates, increasing aeration, incorporating plant residue, and oxidizing  
18 soil organic C. They also reported that CO<sub>2</sub> emissions from soil to atmosphere is the first  
19 process of C loss from the soil and provides an initial indication of C sequestration in the  
20 soil when management practices changes the soil organic C. A range of C sequestration  
21 studies have been published in the past decade, and all of those mainly from upland  
22 cropping, were conducted over one year or longer. Although it is not possible to make

1 direct comparisons between the data describing C sequestration in this study and reported  
2 values, as we calculated soil C sequestration using the C budget method.

3

4 The net primary production in this study varied from 499 to 530 g C m<sup>-2</sup> and this variation is  
5 non significant (Table 4). The values were higher than most of the reported NPP values for  
6 maize, grass, soybean, onion and wheat in Mikasa, central Hokkaido fields were 180, 218, 304,  
7 349 and 454 g C m<sup>-2</sup>, respectively [29]. Omura *et al.* [33] estimated NPP (ground truth data)  
8 from paddy fields of Toyama, Akita, Niigata and Yamagata in Japan were 1445, 1563, 1572  
9 and 1738 g m<sup>-2</sup> (dry matter wt.) respectively. Those values were higher than that of our  
10 investigated NPP 1182 to 1306 g m<sup>-2</sup> (dry matter wt.). For example, Shinano *et al.* [34]  
11 reported that NPP value for 100 kg N ha<sup>-1</sup> fertilized rice and maize in Hokkaido university farm  
12 were 632 and 812 g C m<sup>-2</sup>, respectively, whereas it was 170, and 337 g C m<sup>-2</sup>, respectively for  
13 these crops in the absence of N fertilization. Moreover, Lamptey *et al.* [35] reported that NPP  
14 value for 300 kg N ha<sup>-1</sup> fertilized maize was 859 g C m<sup>-2</sup>, whereas it was 455 g C m<sup>-2</sup> in the  
15 absence of N fertilization. Those values of NPP from N fertilized rice and maize was higher  
16 than that of our investigated fields. The amount of C harvested as grain ranged from 266 to 298  
17 g C m<sup>-2</sup>, accounting for 53–56% of the respective NPP. In other words, about 44 to 47% of the  
18 NPP was incorporated into soil. NPP is amount of C fixation by vegetation and an important  
19 parameter to estimate C balance [36].

20

#### 21 **4.2. Greenhouse gas fluxes ( $R_m$ , $CH_4$ and $N_2O$ )**

22

23 The activity of the soil microbial populations must have differed considerably to account for  
24 the observed water and residues managements. Relationship between the amount of rice

1 residue and seasonal total  $R_m$  which is in agreement with the findings of [Li et al. \[3\]](#). However,  
2 single drained fields D<sub>3</sub>-S showed approximately 17 to 21% lower  $R_m$  than that of multiple  
3 drained fields D<sub>1</sub>-M and D<sub>2</sub>-M, respectively. Management practices play an important role in  
4 influencing losses of C by respiration. Respiration by soil microflora and fauna also contribute  
5 a major portion of CO<sub>2</sub> emission from the soil observed by [Sainju et al. \[23\]](#).

6

7 We presume that the differences in soil microbial activity occurred mostly during the  
8 drainage as a result of anoxic soil in the submerged conditions versus the aerated soil  
9 status during drainage period [37]. Microbial respiration ( $R_m$ ) were recorded from paddy  
10 soils in this study shows an almost two fold variation in fluxes, ranging between 422 and  
11 519 g C m<sup>-2</sup> yr<sup>-1</sup> (Table 3), indicating the rates of  $R_m$  altered by agricultural management  
12 operations like water regime [27]. The  $R_m$  from D<sub>1</sub>-M, D<sub>2</sub>-M and D<sub>3</sub>-S (497, 519 and 422  
13 g C m<sup>-2</sup> yr<sup>-1</sup>, respectively) fields was higher than the reported [28]  $R_m$  for fertilized bare  
14 onion fields (188 to 222 g C m<sup>-2</sup> yr<sup>-1</sup>) in Mikasa, Hokkaido. Moreover, [Mu et al. \[29\]](#)  
15 reported that  $R_m$  from grassland, wheat, onion, maize and soybean fields in Mikasa, Japan  
16 were 301, 328 to 568, 393, 346 and 464 g C m<sup>-2</sup> period<sup>-1</sup> (late March to mid December),  
17 respectively.

18

19 Compared to the D<sub>3</sub>-S field than the D<sub>1</sub>-M and D<sub>2</sub>-M fields, the annual cumulative CH<sub>4</sub>  
20 emissions were about 52% higher in D<sub>3</sub>-S field due to differences in crop residue and  
21 drainage effect. Methane emissions increased with increased rice straw addition, which  
22 matches the results of many researchers [38,39,15] and our previous study [5]. The D<sub>3</sub>-S  
23 field showed the maximum efficiency of the CH<sub>4</sub> emissions, which resulted in the large

1 CH<sub>4</sub> emissions under the single drainage system compared to double drainage (D<sub>1</sub>-M and  
2 D<sub>2</sub>-M) fields during the rice growing season. Lesser residues and multiple drainage  
3 systems reduce the CH<sub>4</sub> emissions by 33 to 34% compared with single drainage. The  
4 published data collection of CH<sub>4</sub> emissions from the major rice growing areas of Asia  
5 shows that the average CH<sub>4</sub> flux with single and multiple drainage, is 60 and 52%,  
6 respectively. So, organic amendments and the water regime are the two variables  
7 controlling the CH<sub>4</sub> flux in the rice growing season.

8

9 We found very low N<sub>2</sub>O emission during the rice growing season, even though those fields  
10 received huge amount of rice straw and different water management. Straw incorporation  
11 tended to decrease N<sub>2</sub>O emissions during the rice-growing season [42,43]. The observed  
12 decreases in N<sub>2</sub>O during the rice-growing season in the presence of straw incorporation may be  
13 explained by the following: the decomposition of crop residues with a high C:N ratio can  
14 enhance microbial N immobilization, resulting in less available N for nitrification and  
15 denitrification and consequently decreased N<sub>2</sub>O emissions [44,45]. In fact there is some  
16 evidence that N<sub>2</sub>O emissions from rice fields could even be reduced by high straw amendments  
17 [46,47,48]. In contrast, incorporation of plant residues has frequently been observed to promote  
18 N loss [49,50]. Granli & Bøckman [51] reported that when soil is submerged continuously with  
19 a water layer, nitrification proceeds slowly, while denitrification proceeds increasingly towards  
20 N<sub>2</sub>, and N<sub>2</sub>O diffusion in soil is severely hindered by the water layer. It has been generally  
21 thought that the emission rate of N<sub>2</sub>O from rice paddy field to the atmosphere was very low.  
22 Generally, low N<sub>2</sub>O fluxes are found during flooded periods, whereas high N<sub>2</sub>O fluxes are  
23 found during temporal drained periods [52,53,54,55].

1 In this study, investigated paddy fields were under farmers' actual management  
2 conditions where various water regime and different amount of crop residue from  
3 previous crop were present. Although water management that included multiple and  
4 single drainage might have interrupted the trend of GHGs emission in this study. Hadi *et al.*[56] observed that, the reductions of GHGs emission from Japanese peaty and alluvial  
5 paddy soil due to intermittent drained were about 32 and 37%, respectively. Our results  
6 do not refute the findings of other studies where water management was a key factor in  
7 reducing GHGs emissions from paddy. But we emphasize that the environmental  
8 conditions of central Hokkaido in association with crop-residue management favored  
9 GHGs release into the atmosphere [5,29]. However, the fact remains that the mineral-soil  
10 dressing on peat could have a significant impact to suppress GHGs emission from  
11 beneath the peat reservoir.

13

#### 14 ***4.3. Combined climatic impact of CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O***

15

16 Research on GWP of paddy ecosystem, including rice growing and fallow period is very  
17 limited. Earlier Zou *et al.* [57] calculated GWPs using IPCC factors [58] to assess the  
18 combined climatic impacts only from CH<sub>4</sub> and N<sub>2</sub>O emissions in rice paddies under various  
19 agricultural practices and not CO<sub>2</sub> emission in their estimation. Moreover, Xiao *et al.* [7]  
20 estimated net GWP (g CO<sub>2</sub> equivalent m<sup>-2</sup> yr<sup>-1</sup>) in paddy field where the GWP of N<sub>2</sub>O and CH<sub>4</sub>  
21 emission estimation procedure were quite similar to the values estimation in the present study  
22 (Table 7). Thus, the major difference in the net GWP between their study and ours resulted  
23 exclusively from the difference in GWP<sub>CO<sub>2</sub></sub> estimation. In our study for computation of  
24 GWP<sub>CO<sub>2</sub></sub> emission were based on the C budget method. Robertson *et al.* [59] and Six *et al.* [60]  
25 observed that the change in soil organic C (SOC) or soil respiration should be measured for

1 accounting of GWP of soils. *Six et al.* [60] and *Yu & Patrick* [61] computed the GWP of  
2 different soils by measuring the changes in SOC storage. The IPCC [8] also suggest calculating  
3 GWP using the same approach.

4  
5 The annual net GWP values from three paddy fields in this study were higher than those  
6 for paddy and upland crop in other studies. *Hadi et al.* [56] reported that net GWP from  
7 intermittently drained paddy fields in South Kalimantan, Indonesia was 2091 (g CO<sub>2</sub>  
8 equivalent m<sup>-2</sup> growing season<sup>-1</sup>). Moreover, *Wu et al.* [62] reported that the net GWPs  
9 was 890 g CO<sub>2</sub> -equivalent m<sup>-2</sup> yr<sup>-1</sup> for the field which was flooding during the rice  
10 season but with drainage during the midseason and harvest time. *Mu et al.* [29] estimated  
11 net GWP for seven upland cropping systems in Mikasa, central Hokkaido, Japan ranged  
12 from 749 to 1790 (g CO<sub>2</sub> equivalent m<sup>-2</sup>-late March to mid December), where CO<sub>2</sub>  
13 emission contributed to 84 to 99% of the net GWP. Those values are lower than that of  
14 our study. The trend of increase in net GWP mainly govern by the trend of CH<sub>4</sub> emission  
15 from the studied fields. The fields with positive net GWP in this study showed annual  
16 GWP<sub>CH<sub>4</sub></sub> accounted for 71.9 to 86.1% of the annual net GWP. In seasonal aspect,  
17 GWP<sub>CH<sub>4</sub></sub> contributed 100% to the annual net GWP mainly from the rice growing period.  
18 On the other hand, GWP<sub>CO<sub>2</sub></sub> and GWP<sub>N<sub>2</sub>O</sub> contributed 81 to 99% and 73 to 79%,  
19 respectively from winter-fallow season. Methane has been reported to account for 95% of  
20 total CO<sub>2</sub>-equivalent emissions from paddy fields based on GWP [63]. *Xiao et al.* [7]  
21 reported that the annual net GWP (g CO<sub>2</sub> equivalent m<sup>-2</sup>) in paddy field was estimated to  
22 be 640 to 1124, and CH<sub>4</sub> emission contributed to 90 to 99% of the net GWP. Those  
23 results indicated that CH<sub>4</sub> dominated the rice paddy's positive net GWP, whereas CO<sub>2</sub>

1 dominated for the upland crops. The proportion of contribution (%) from individual GHG  
2 basis GWP to net GWP of CO<sub>2</sub>, CH<sub>4</sub>, and N<sub>2</sub>O were 13.8 to 26.5, 71.9 to 86.1 and 0.13 to  
3 1.61, respectively. This indicates that CH<sub>4</sub> was a major GWP contributor in paddy field  
4 and was regulated by management practices especially residue and water regimes.  
5 However, the net GWP was dominated by CH<sub>4</sub> emissions, consistent with the findings of  
6 previous studies [64,65,66].

7  
8

## 5. Conclusion

9 Paddy-fallow cropping systems could be sources of atmospheric CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O. C  
10 sequestration showed negative values i.e., C loss for all the paddy fields. C loss can not be  
11 compensated for by NPP due to the impact of residue management followed by water  
12 management on C fluxes (CO<sub>2</sub>-C and CH<sub>4</sub>-C). The annual GWP<sub>CH<sub>4</sub></sub> accounted for 69.4 to  
13 84.6% of the annual net GWP and this contribution occurred entirely during the rice growing  
14 period. These results indicate that CH<sub>4</sub> dominated the rice paddy's net GWP. The method of CS  
15 estimation described in this study will help to make progress in measurements of C input and  
16 loss from paddy soils and will provide us with more accurate ways of assessing changes in soil  
17 C stocks and, thus, should reduce the uncertainties that underlie predictions of soil C stocks in  
18 paddy ecosystems. The present study implied that paddy field is more potent to loss of C rather  
19 than C store. However, management practices like residue and water regime may be the major  
20 options to control C budget in paddy-fallow ecosystems.

21 **Author Contributions:** H.M.N., O.N. and R.H. conceived and designed the experiments; H.M.N. and  
22 O.N. performed the experiments; H.M.N., O.N. and S.S. analyzed the data; all of the authors  
23 contributed reagents/materials/analysis tools and wrote the paper.

24 **Acknowledgments:** This study was partly supported by the Global Environment Research Program of the  
25 Ministry of the Environment of Japan (No. S3-3a). In addition, we would like to thank Satsuki Tamura for  
26 her cooperation during this study and Tahsin Sakif for his English checking.

9 Table 5. Annual C sequestration from paddy-fallow cropping systems.

Site <sup>§</sup>	NPP (whole plant) (g C m <sup>-2</sup> )	Grain yield (g C m <sup>-2</sup> )	Annual emission		C sequestration <sup>†</sup> (g C m <sup>-2</sup> yr <sup>-1</sup> )
			R <sub>m</sub> (g C m <sup>-2</sup> yr <sup>-1</sup> )	CH <sub>4</sub> (g C m <sup>-2</sup> yr <sup>-1</sup> )	
D <sub>1</sub> -M	499	266	497	75.5	-339
D <sub>2</sub> -M	529	298	519	76.8	-365
D <sub>3</sub> -S	530	297	422	116	-305

11 <sup>§</sup> D<sub>1</sub>-M (drainage-multiple); D<sub>2</sub>-M (drainage-multiple); D<sub>3</sub>-S (drainage-single).

12 <sup>†</sup> C sequestration = NPP - (R<sub>m</sub> + CH<sub>4</sub> + grain harvest + straw harvest)

13 Note: all harvested straw leftover on three fields, i.e., straw harvest = 0. Negative values of C sequestration indicate net CO<sub>2</sub> emission  
14 from soils.

15  
16  
17 Table 6. Seasonal CS or C loss and their contribution to annual CS or C loss.

Site <sup>§</sup>	CS in growing season <sup>†</sup>	CS in winter- fallow season	CS yr <sup>-1</sup> (g C m <sup>-2</sup> yr <sup>-1</sup> )	Proportion of contribution to annual C loss from G or F <sup>†</sup> (%)
	(g C m <sup>-2</sup> season <sup>-1</sup> )	(g C m <sup>-2</sup> season <sup>-1</sup> )		
D <sub>1</sub> -M	-116	-223	-339	66 from F
D <sub>2</sub> -M	-130	-235	-365	64 from F
D <sub>3</sub> -S	-116	-188	-305	62 from F

19 <sup>§</sup> D<sub>1</sub>-M (drainage-multiple); D<sub>2</sub>-M (drainage-multiple); D<sub>3</sub>-S (drainage-single). <sup>†</sup>G, rice growing season.

20 F, winter-fallow season. <sup>†</sup> C sequestration (CS growing season<sup>-1</sup>) = NPP - (R<sub>m</sub> + CH<sub>4</sub> + grain harvest). C sequestration (CS winter-  
21 fallow<sup>-1</sup>) = - (R<sub>m</sub> + CH<sub>4</sub> + straw harvest). Note: all harvested straw leftover on four fields, i.e., straw harvest = 0. Negative values of  
22 C sequestration indicate net CO<sub>2</sub> emission from soils.

1 Table 7. Seasonal GWP (g CO<sub>2</sub> equivalent m<sup>-2</sup>) of CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O and their contribution to annual  
2 GWP.

Site <sup>§</sup>	GWP during rice growing season			GWP during winter-fallow season			Annual GWP of individual GHG gas basis			Proportion of contribution from G or F <sup>†</sup> to annual GWP of respective gas (%)		
	CO <sub>2</sub> <sup>‡</sup>	CH <sub>4</sub>	N <sub>2</sub> O	CO <sub>2</sub> <sup>‡</sup>	CH <sub>4</sub>	N <sub>2</sub> O	CO <sub>2</sub> <sup>‡</sup>	CH <sub>4</sub>	N <sub>2</sub> O	CO <sub>2</sub>	CH <sub>4</sub>	N <sub>2</sub> O
D <sub>1</sub> -M	149	2819	10.2	817	-0.70	27.7	967	2818	38.0	85 F	100 G	73 F
D <sub>2</sub> -M	196	2867	15.1	861	1.46	49.2	1057	2868	64.3	81F	100 G	77 F
D <sub>3</sub> -S	3.52	4312	1.36	689	4.45	5.23	693	4317	6.59	99 F	100 G	79 F

3 <sup>§</sup> D<sub>1</sub>-M (drainage-multiple); D<sub>2</sub>-M (drainage-multiple); D<sub>3</sub>-S (drainage-single).

4 <sup>‡</sup> GWP of CO<sub>2</sub> = - (CS + CH<sub>4</sub> flux) × (44/12). <sup>†</sup>G, rice growing season. F, winter-fallow season.

5

6

7

8

9 Table 8. Proportion of contribution from seasonal net GWP and annual GWP of individual GHG  
10 to annual net GWP.

Site <sup>§</sup>	Net GWP (g CO <sub>2</sub> eq. m <sup>-2</sup> season <sup>-1</sup> )		Proportion of contribution from G or F <sup>†</sup> to annual net GWP (%)	(g CO <sub>2</sub> eq. m <sup>-2</sup> yr <sup>-1</sup> )			Annual net GWP	Proportion of contribution from individual GHG basis GWP to net GWP (%)		
	growing season	winter-fallow season		Annual GWP of individual GHG basis				CO <sub>2</sub> <sup>‡</sup>	CH <sub>4</sub>	N <sub>2</sub> O
				CO <sub>2</sub> <sup>‡</sup>	CH <sub>4</sub>	N <sub>2</sub> O		CO <sub>2</sub> <sup>‡</sup>	CH <sub>4</sub>	N <sub>2</sub> O
D <sub>1</sub> -M	2978	844	78 from G	967	2818	38.0	3823	25.3	73.7	0.99
D <sub>2</sub> -M	3078	911	77 from G	1057	2868	64.3	3990	26.5	71.9	1.61
D <sub>3</sub> -S	4317	699	86 from G	693	4317	6.59	5016	13.8	86.1	0.13

11 <sup>§</sup> D<sub>1</sub>-M (drainage-multiple); D<sub>2</sub>-M (drainage-multiple); D<sub>3</sub>-S (drainage-single).

12 <sup>‡</sup> GWP of CO<sub>2</sub> = - (CS + CH<sub>4</sub> flux) × (44/12). <sup>†</sup>G, rice growing season; F, winter-fallow season.
