# Achieving Net Zero Carbon Dioxide by Sequestering Biomass Carbon

Jeffrey A. Amelse <sup>1,2</sup><sup>1</sup> CICECO, Aveiro Institute of Materials, Department of Chemistry, University of Aveiro, 3810-193 Aveiro, Portugal; JAmelse@UA.Pt;<sup>2</sup> Independent Contributor, Batavia, IL 60510 USA; AmelseJeff@Gmail.com

Received: date; Accepted: date; Published: date

**Abstract:** Mitigation of global warming requires an understanding of where energy is produced and consumed, the magnitude of carbon dioxide generation, and proper understanding of the Carbon Cycle. The latter leads to the distinction between and need for both CO<sub>2</sub> and biomass CARBON sequestration. Short reviews are provided for prior technologies proposed for reducing CO<sub>2</sub> emissions from fossil fuels or substituting renewable energy, focusing on their limitations. None offer a complete solution. Of these, CO<sub>2</sub> sequestration is poised to have the largest impact. We know how to do it. It will just cost money, and scale-up is a huge challenge. Few projects have been brought forward to semi-commercial scale. Transportation accounts for only about 30% of U.S. overall energy demand. Biofuels penetration remains small, and thus, they contribute a trivial amount of overall CO<sub>2</sub> reduction, even though 40% of U.S. corn and 30% of soybeans are devoted to their production. Bioethanol is traced through its Carbon Cycle and shown to be both energy inefficient, and an inefficient use of biomass carbon. Both biofuels and CO<sub>2</sub> sequestration reduce FUTURE CO<sub>2</sub> emissions from continued use of fossil fuels. They will not remove CO<sub>2</sub> ALREADY in the atmosphere. The only way to do that is to break the Carbon Cycle by growing biomass from atmospheric CO<sub>2</sub> and sequestering biomass CARBON. Theoretically, sequestration of only a fraction of the world's tree leaves, which are renewed every year, can get the world to Net Zero CO<sub>2</sub> without disturbing the underlying forests. Thoughts are put forth on how to achieve secure permanent biomass sequestration.

**Keywords:** carbon dioxide; global warming; sequestration; carbon cycle; biomass sequestration, carbon sequestration

## 1. Introduction

CO<sub>2</sub> is the dominant greenhouse gas component leading to Global Warming. If man does nothing to intervene, atmospheric CO<sub>2</sub> levels are projected to more than double to over 900 ppmv by 2100 (Lindsey, 2020). This paper begins on purpose with a short review of previous proposed solutions to show that none of them are a complete solution to achieve Net Zero CO<sub>2</sub>. Sequestration of biomass carbon, in particular tree leaves, is proposed as a simple (in concept) method to achieve Net Zero CO<sub>2</sub>.

The Carbon Cycle is misunderstood by many. There are those who believe planting more trees will lead to a reduction in atmospheric CO<sub>2</sub>. If one follows trees through their life cycle, trees are sustainable. They do pull CO<sub>2</sub> from the air during their life. However, in unmanaged forests, trees lose their leaves every year, which decompose and release their stored carbon back to the atmosphere. At the end of their life, trees die, decompose, and release the carbon stored in their trunks and

branches. Trees take care of themselves. However, over their entire life and death cycle, they will not lead to a net reduction in CO<sub>2</sub> that is ALREADY in the atmosphere.

Biofuels have been proposed to reduce CO<sub>2</sub> buildup from vehicles. Biofuels do play a role in reducing FUTURE emissions of CO<sub>2</sub> from the burning of fossil fuels that they displace. However, they come at an economic and societal cost. Almost 40% of the U.S. corn crop is devoted to fuel ethanol production. Biofuels would at best be sustainable [18]. However, they are not, when the fuel required to plant, fertilize, harvest, transport the carbon source, and fuel used in the biofuel processes is considered. Bioethanol from corn will be traced through its Carbon Cycle and will be shown to be both energy inefficient, and an inefficient use of biomass for reducing CO<sub>2</sub>. Biofuels from other sources such as cellulosic biomass will be discussed, and a status report will be provided for those technologies.

The technologies for CO<sub>2</sub> sequestration from large industrial furnaces, such as those at power plants will be discussed. The bottom line is: We know how to do it, using modifications of proven technologies that have been used for many years. However, cost and scaleup will be shown to be issues. CO<sub>2</sub> sequestration can reduce FUTURE CO<sub>2</sub> going to the atmosphere from continued burning of fossil fuels. It will be a necessary tool in combatting global warming. However, it will not reduce the CO<sub>2</sub> ALREADY in the atmosphere and unsequestered CO<sub>2</sub> from the continued burning of fossil fuels, which is needed to supply the world's energy demand.

Proper understanding of the Carbon Cycle will show that the only way to reduce the CO<sub>2</sub> ALREADY in the atmosphere is to grow biomass and removed it from the Carbon Cycle. Some thoughts on how to do this will be presented.

First, it is important to understand the energy scene, i.e., what fuels are used and where they are used, and to examine the current world energy consumption by fuel source, and the amount of CO<sub>2</sub> currently being generated each year to understand the magnitude of the problem and to prioritize efforts.

## **2. The Energy Scene**

The U.S. Energy Information Authority (EIA) provides a database that tracks primary energy production and disposition for the U.S., and other world regions [1]. BP provides its yearly Statistical Energy Review [2].

**Fig. 1** shows the U.S. 2016 primary energy source and sector in which the energy is used [1]. The three largest sources are petroleum (37%), natural gas (29%), and coal (15%). The reality is that in 2016 only about 10% of primary energy came from renewables.

The numbers on the left of the lines connecting source to sector show the percentage of a source that goes to a corresponding sector. The major sectors are transportation (29%), industry (22%), and electric power (39%). Industrial use accounts for 22% and residential and commercial accounts for 11%. Renewables accounted for only about 10%.

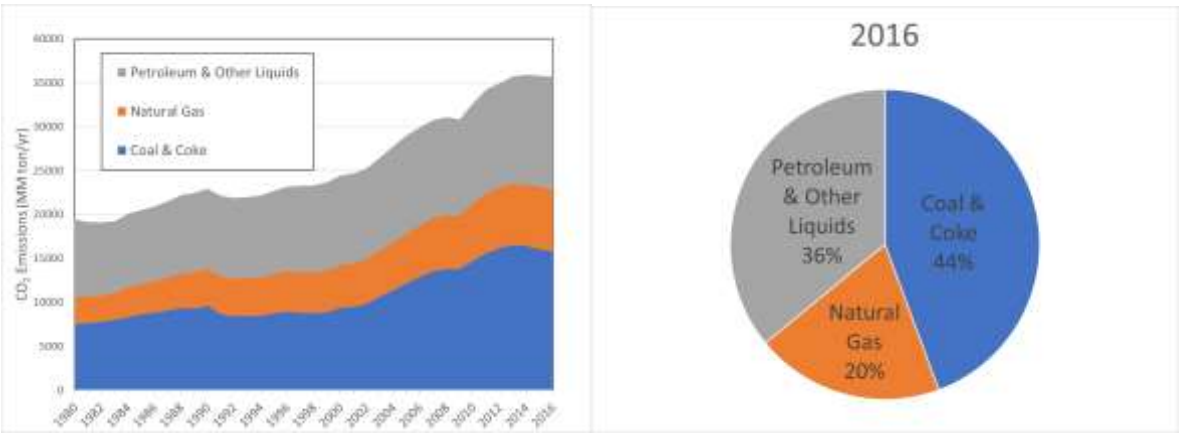

The numbers on the right of **Fig. 1** show the percentage of energy used in a sector that comes from the corresponding source. Thus, 71% of petroleum goes to the transportation section, 23% to industry, and only minor amounts to residential and commercial and electric power sectors. Natural gas usage is split almost evenly amongst industrial, residential and commercial, and electric

power, with very little to transportation. Coal and nuclear are almost exclusively used to generate power.

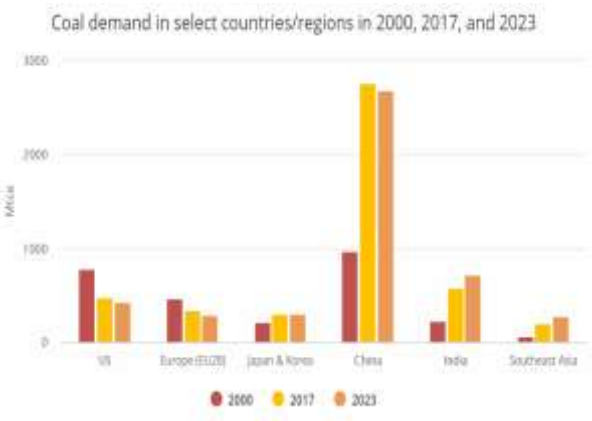

**Fig. 1.** U.S. Primary energy consumption by source and sector, 2016  
Source: U.S. primary consumption, EIA (2017) [1].

**Fig. 2** shows the magnitude of the CO<sub>2</sub> problem. In 2016, CO<sub>2</sub> emissions were 36 Billion tons. The world has a huge CO<sub>2</sub> problem that is going to take a variety of huge solutions. **Fig. 1** shows the U.S. energy demand. World energy demand is different. In particular, coal represents a much higher fraction of energy demand in China. China dominates world energy demand, and thus, it is not surprising that coal and coke (a heavy ends solid refinery byproduct that can be substituted for coal) represents the largest source of CO<sub>2</sub> emissions, as shown in **Fig. 3** , and that Asia and Oceania represented almost 50% of world CO<sub>2</sub> emissions in 2016 (**Fig. 4** ) Coal usage in China exceeds that in the rest of the world combined, as shown in **Fig. 5**.

**Fig. 4.** 2016 CO<sub>2</sub> Emissions by Region

**Fig. 5.** Coal demand in select countries/regions in 2000, 2017, and 2023.  
Data Source (EIA, 2017). All Rights Reserved. [1]

**Fig. 6** shows 2018 U.S. primary energy consumption by source. It has changed little from 2016. This Figure also shows a detailed breakdown of renewables energy. In 2018, biofuels accounted for only 20% of renewables energy, which account for only 11% of total U.S. energy demand. As shown in **Fig. 1**, 92% of energy for transportation came from petroleum, and 37% of petroleum went to transportation. It is impractical to sequester CO<sub>2</sub> from vehicles. A partial answer for CO<sub>2</sub> from vehicles has come from biofuels. Biofuels do replace CO<sub>2</sub> from fossil fuels with renewable CO<sub>2</sub> coming from biomass grown from CO<sub>2</sub> pulled from the atmosphere by photosynthesis. However, tracing bioethanol through its Carbon Cycle will show it to be energy inefficient and an inefficient use of biomass carbon. Thus, a CO<sub>2</sub>-free energy source is needed to supply transportation. Finding a CO<sub>2</sub>-free source of energy for transportation would also take care of reducing CO<sub>2</sub> from petroleum. A typical large complex U.S. refinery converts a medium heavy sour crude into about 6% lights (LPG), 47% gasoline, 33% distillates, and 14% heavies (heavy fuel oil, coke, and asphalt) [3]. Distillates include diesel, kerosene, and jet fuel. European refineries produce more diesel and less gasoline. As noted above, overall, 71% of petroleum went to transportation in 2016.

**Fig. 6** also shows the EIA projection for energy source shifts out to 2050. The fraction of energy from renewables is projected to double. The Figure shows detail on where the renewables growth is assumed to come from. The absolute amount of electricity from wind is projected to double. Solar is projected to increase by a factor of 9. Is that a reasonable projection? For a stark reality of the promise and deception of renewables, see the recent film “Planet of the Humans” available on YouTube [4]. If it is to come at the residential level, it would require huge individual homeowner investment. Natural gas has become cheap and abundant in the U.S. after the advent of fracking. EIA projects that the fraction of electricity coming from natural gas remains about constant out to 2050. It is still a very significant percentage and a significant percentage of CO<sub>2</sub> production. Thus, a means to sequester CO<sub>2</sub> during the production of electricity from natural gas is needed, especially if the projected increase of electricity from solar falls short.

**Fig. 6.** Electricity generation from selected fuels and breakdown of where the future growth in renewables is projected to come from

Source: (EIA, 2020). All Rights Reserved. [58]

Will projections for a great increase in renewables energy come true? R. Malhorta of The Stanford Research Institute (SRI) said the world will need the equivalent energy from 7-9 cubic miles of oil to satisfy the incremental world energy needs to the year 2050 [5]. He argues that renewables cannot provide a complete solution to those needs stating that just 1 (of 7-9 needed) cubic mile of oil would require:

- 200 hydroelectric dams the size of the 3 Gorges dam  
(1 every quarter for 50 years)
- 2500 nuclear plants the size of the Diablo Canyon reactor  
(1 per week for 50 years)
- 7700 solar panel parks 10 x the world's largest  
(3 per week for 50 years)
- 3 million windmills  
(1200 per week for 50 years)
- 4.2 billion solar roofs  
(250k roofs per day for 50 years)

Thus, he argues it is impractical to think that petroleum and coal can be displaced completely. That is reality! Energy reduction alone cannot get the world to Net Zero CO<sub>2</sub>. In fact, world energy

demand will increase with increase in population, despite energy conservation efforts. Clearly, other solutions are needed.

### 3. Understanding the Carbon Cycle

A cartoon depicting the Carbon Cycle is provided in **Fig. 7**. Plants get essentially all of their carbon for their growth from CO<sub>2</sub> in the atmosphere via photosynthesis, forming carbohydrates [6]. The photosynthesis reaction can be represented crudely by the reaction:

The simplest formula representation of carbohydrates is CH<sub>2</sub>O.

Plant matter is fed to animals and plants and animals are fed to humans. Animals and humans respire the bulk of the carbon in their food as CO<sub>2</sub> when they exhale. Animals and humans grow and thus serve as temporary storage vessels for some of the carbon. However, plants, animals, and humans eventually die and decompose and release their carbon back to the atmosphere as CO<sub>2</sub>, completing their part of the Carbon Cycle. Plants and animals that fall to the ground or are buried (such as corn silage) decompose via the action of worms, fungi, and bacteria. They feed on the decomposing plants, and respire CO<sub>2</sub>, and thus, play an important role in the Carbon Cycle. Normally there is no net buildup of carbon in the soil. Soil carbon generally reaches a steady state carbon level of 1-4 weight percent (wt%) [7].

**Fig. 7** The Carbon Cycle.

Source: Alamy (2020) The Carbon Cycle [8].

While plants receive all of their carbon from the atmosphere, they draw water as a source of hydrogen, nitrogen, phosphorous and other nutrients such as potassium from the soil. The enzyme that catalyzes photosynthesis contains both nitrogen and phosphorous [9]. In the natural Carbon Cycle, dead plant material returned to the soil feeds the worms, bacteria, and fungi that decompose

plant matter releasing the needed N, P, K, and other nutrients back into the soil. That is part of the cycle. Intensive farming requires artificial fertilizer to provide some of the nutrients. Thus, the normal Carbon Cycle is sustainable. There is no net movement of CO<sub>2</sub> in the atmosphere and no net movement of carbon into the ground. The only way to remove CO<sub>2</sub> ALREADY in the atmosphere is to break the cycle. Biomass must be grown from CO<sub>2</sub> in the atmosphere and the biomass itself must be sequestered (CARBON sequestration, not CO<sub>2</sub> sequestration).

#### **4. Bioethanol and The Carbon Cycle**

The Kyoto Protocol was adopted on December 11, 1997 and entered into force on February 16, 2005 [10]. It called for major industrial countries to reduce emissions of greenhouse gases.

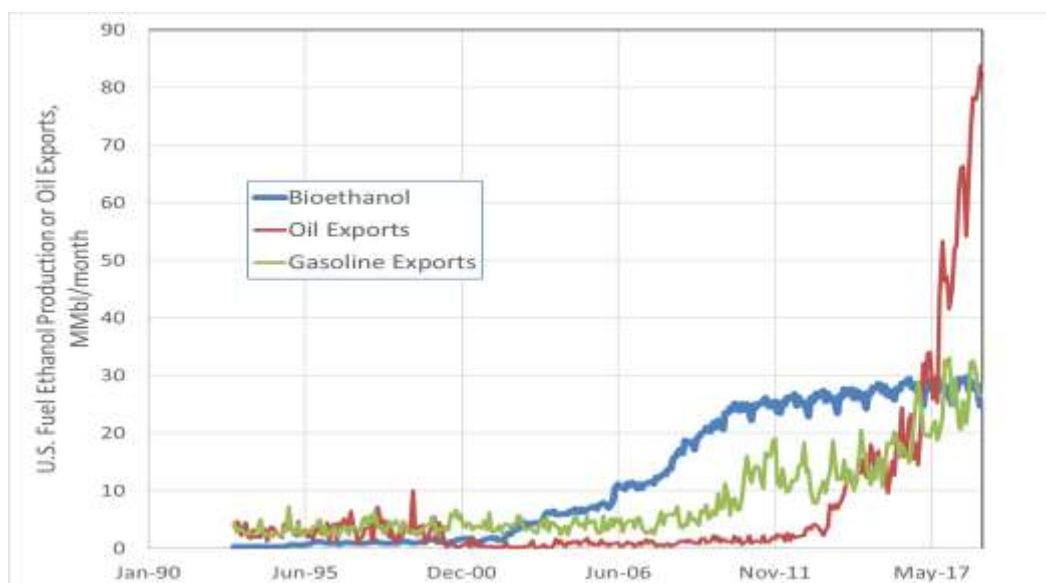

The European response was to shift from gasoline to diesel at the lobbying of the major auto companies. Diesel engines do provide better fuel economy than gasoline vehicles. However, diesel vehicles have issues with emissions of carcinogenic particulates and NOX. We now know that some European car manufacturers cheated on emissions testing, and diesel engines have contributed to health issues [11].

The U.S. refineries were configured to make gasoline, with large catalytic reformer and Fluid Catalytic Cracking (FCC) capacity installed in the 1960's and 1970's to make high octane gasoline in response to lead phase out. Thus, the U.S. remained in favor of gasoline. To meet the requirements of the protocol, the U.S. mandated the blending of bioethanol. The gasoline pool has reached the "blending limit," such that essentially 10% of the U.S gasoline pool is bioethanol [12]. 10 vol% is the limit for normal gasoline because ethanol is corrosive and degrades elastomers in gaskets of normal gasoline engines. Flex fuel vehicles are now sold that can accept E85 (85% ethanol), but E85 is not widely available and has not been widely adopted by the public.

One of the claimed benefits for bioethanol is that the U.S. would become less dependent on foreign oil. With the advent of fracking to release tight oil and gas, and the discovery of oil in the western U.S., the U.S. has become the largest producer of oil in the world, and now exports about as much finished gasoline and much more oil than the amount of bioethanol blended into gasoline as shown in **Fig. 8** [12-15]. Thus, the argument that bioethanol is needed for U.S. energy independence no longer holds.

Another early argument for bioethanol was that blending oxygenates into gasoline would reduce tail pipe emissions of carbon monoxide (CO). However, a study in Mexico City converters showed no indication that CO emissions are reduced with increasing oxygenate concentration for vehicles with 3-way converters [16]. Everything that goes into the converters comes out clean.

In the U.S. essentially all of bioethanol is made from corn. However, as noted above, transportation is only a fraction of primary energy sector demand, and gasoline is only a fraction of transportation, such that bioethanol represents only about 1.7% of total U.S. energy consumption. Biodiesel penetration is even lower at about 3% of diesel, which is only a fraction of distillates which are lower volume than gasoline in the U.S. [17].

**Fig. 8.** U.S. bioethanol used in gasoline (blue), oil exports (red), and gasoline exports (green)  
Data Sources: EIA [12-15].

Bioethanol production comes at great economic and social cost and has other issues. The U.S. Department of Agriculture (USDA) indicates that about 40% of the U.S. corn crop is devoted to bioethanol production [18]. That is diverting a lot of potential food into gas tanks! There are other issues. Bioethanol is hygroscopic. It picks up water in pipelines. It must be blended near gas stations. This adds both capital, labor, and energy costs.

Let me repeat, plants get all of their carbon from CO<sub>2</sub> in the air via photosynthesis. Let's track that carbon through the bioethanol production and Carbon Cycle.

Do you know how much air containing only 400 ppmv of CO<sub>2</sub> is required to produce an acre of corn? The answer may surprise you. The calculation is provided in a spreadsheet in Section **SI.1**. It takes the air above about 0.85 acres of land up to the edge of the troposphere (35,000 ft) to feed the growth of one acre of corn. In 2019, 89.7 million acres of corn were planted in the U.S. [18]. The U.S. land area is 2.43E9 acres. Thus, while corn is the largest crop in the U.S. only about 3.7% of the U.S. land area is devoted to corn. Of course, not all U.S. land and an even lower fraction of total world land is suitable for growing corn [19]. Thus, it is not reasonable to expect that corn ethanol production can be increased much further.

Corn ethanol is produced by converting starch in corn kernels to sugar and fermenting the sugar to ethanol. Starch is a polymer of the 6-carbon sugar glucose. It occurs in two forms, amylose, a smaller linear polymer, and amylopectin, a larger branched polymer (**Fig. SI6**). Polymerization occurs by condensing two glucose molecules releasing water. Starch is converted to sugars by the reverse reaction, catalyzed by enzymes. The glucose sugar is then fermented to form bioethanol.

The processes for converting corn starch to sugars and then fermenting to bioethanol are discussed below. A process flow diagram for the current more economic corn ethanol process, the Dry Grind Ethanol Process is shown in **Fig. 10**.

Fig. 9. Amylose and Amylopectin polymers of glucose in corn starch

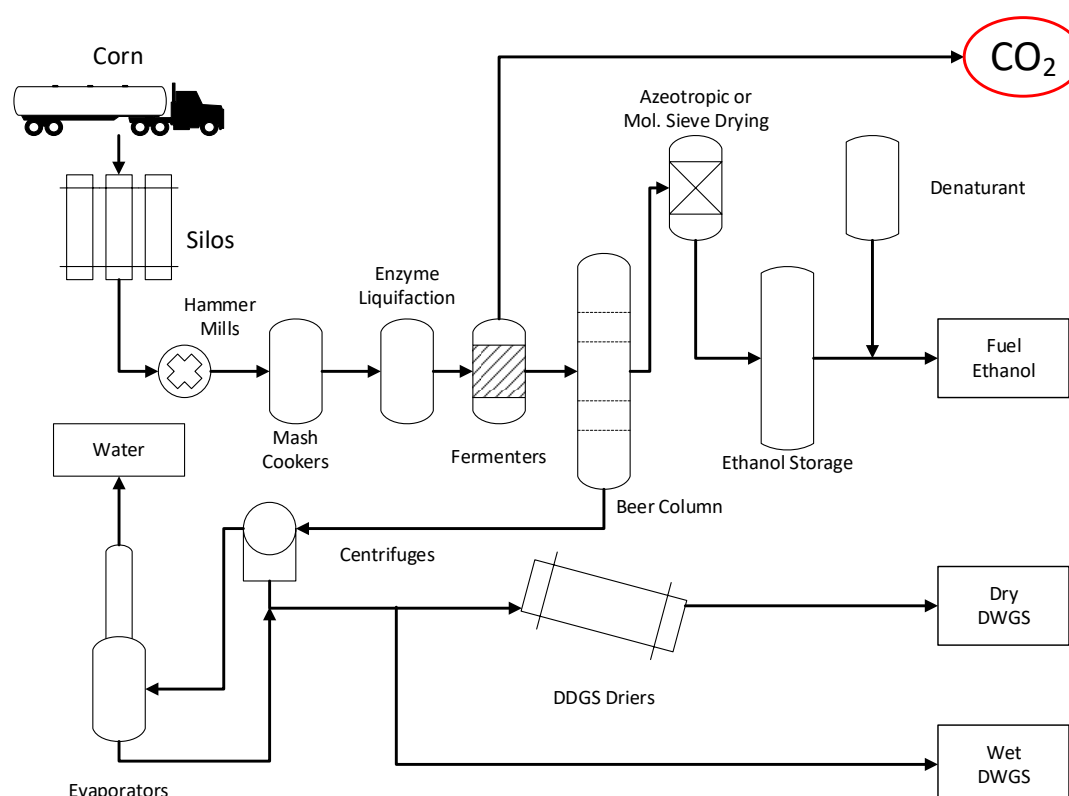

Fig. 10. A Dry Grind Corn Ethanol Plant

CO<sub>2</sub> is shown as a product of the Dry Grind Process in Fig. 10. Why?

The simplified molar formula for starch is C<sub>6</sub>H<sub>10</sub>O<sub>5</sub>, and hydrolysis to glucose can be represented as:

(1.00 gm starch → 1.11 gm glucose)

The glucose is fermented to ethanol via the reaction:

1.11 gm → 0.568 gm + 0.542 gm

Thus, fermentation converts 2 of the 6 carbons in glucose to CO<sub>2</sub>, before the ethanol does any useful work in a gasoline engine. CO<sub>2</sub> liberation during fermentation is why champagne is bubbly!

There are over 200 ethanol plants in the U.S. [20]. CO<sub>2</sub> sequestration is possible by absorption or adsorption. However, only a handful recover CO<sub>2</sub>. The rest vent to atmosphere, because recovering CO<sub>2</sub> is expensive, the value of the CO<sub>2</sub> byproduct is low, and most of these plants are in remote regions away from a destination for the CO<sub>2</sub> product. That is reality!

One can already see why corn ethanol is a very inefficient use of the carbons in the corn plant biomass to displace fossil fuel carbons. However, corn kernels are only about 60 wt% starch and the corn plant is only about 35 wt% corn kernels [21]. What happens to the rest of the corn plant carbon as it completes its Carbon Cycle? Most is plowed back into the ground, where it decomposes and releases its carbon back to the atmosphere.

Let's take a look at the amount of energy required to separate the water from the alcohol. Water and ethanol form an azeotrope. Thus, it is not possible to use simple distillation to meet the water specification for fuel grade ethanol. It requires either azeotropic distillation or drying over molecular sieves. Older plants used azeotropic distillation. U.S. Patent Number 4,217,178 discloses a heat integrated ethanol plant with azeotropic distillation [22]. The energy requirement for the distillations is 239.4 kJ/gm mol ethanol. The heat of combustion of ethanol is 1360 kJ/gm mol. Thus, the azeotropic distillation step alone requires 17.8% of the heat of combustion of the product. A full economic model of a Dry Grind ethanol plant, including all utilities costs is provided in Kwiatkowski, et al. [23]. The modeled plant uses a molecular sieve drier after distilling the beer to near the azeotrope. That is lower energy than azeotropic distillation. However, with steam cost converted to natural gas equivalent, the total plant natural gas equivalent usage that is 87% higher than the azeotropic steam heat of US 4,217,178. Even though steam for the beer column alone will be less than the azeotropic distillation step, the total plant needs heat elsewhere (cooking the mash, drying the DDGS, etc.) Thus, bioethanol production is not only an inefficient use of corn biomass carbon, but parasitic energy costs are high.

Corn ethanol is not currently economic without huge government subsidies of over \$1/gallon, or billions of taxpayer dollars per year [24]. It is not the intent of this paper to pass judgements on cost. Rather, one must be aware of true costs of production. So, what can bioethanol plants do better to reduce CO<sub>2</sub> going to the atmosphere? There should be a mandate to recover the CO<sub>2</sub> vented from the fermenters, and the cost of sequestration must be borne by the consumers of gasoline. Or better yet, an alternate solution to hydrocarbon-fueled vehicles must be found.

How much CO<sub>2</sub> can be sequestered from U.S. bioethanol production? U.S. nameplate ethanol production is 16,868 MMgal/yr [18]. With 2 mol CO<sub>2</sub> generated per mol of ethanol, sequestering all of the CO<sub>2</sub> would remove 106 MM tons/year CO<sub>2</sub>. This is a big number, but only 0.3% of the amount of the 36,000 MMtons/yr CO<sub>2</sub> generated each year worldwide. Thus, other solutions are needed.

What if the U.S. corn plants used to produce ethanol were permanently sequestered? Corn production in the U.S. peaked in the 2017/2018 season at 14,609 MMBushels, with 38.4% going to fuel ethanol. At 35 wt% corn kernels, the weight of corn plants devoted to ethanol was 1.17 billion tons [18]. Representing corn as CH<sub>2</sub>O, secure burial of those corn plants would have pulled 406.9 MM metric tonnes of CO<sub>2</sub> from the atmosphere compared to world CO<sub>2</sub> production of 36 billion tons or 1.1%. Thus, simply burying the corn plants would be a more efficient means of pulling CO<sub>2</sub> ALREADY in the atmosphere, compared to corn ethanol, which is less than sustainable. However,

this is nowhere close to what is needed to keep up with the CO<sub>2</sub> entering the atmosphere from the burning of fossil fuels. Thus, the U.S. cannot farm its way out of the CO<sub>2</sub> problem.

The U.S. and Brazil account for about 85% of the world ethanol production. Brazil uses cane sugar as the main raw material, and the energy efficiency of those plants is improved by burning bagasse (waste after squeezing out the cane syrup) to generate power. However, Google pictures of Brazil ethanol plants and you will see that burning bagasse is very dirty and pollution generating, and there is a huge negative environmental impact of clear-cutting forests to grow sugar cane.

## **5. Cellulosic Bioethanol**

Cellulosic ethanol has been touted as the Holy Grail for bioethanol. Advantages would be cheap, non-food feedstock. However, its implementation has been slow. A Sandia study indicated that 70 billion gallons of cellulosic ethanol should be “possible” by 2030 [25]. However, only about 15 MM gal were produced in 2018 [26]. That is reality! Why? There are continued economic and technical challenges.

A dated study estimated capital and production costs for a cellulosic ethanol plant [47]. The cost challenge as of 2011 was:

Current Ethanol Sales Price:	\$2.15
Ethanol Yield	79 gal/ton (76% efficiency)
Ethanol Production Volume	61.0 MM gal/yr
Capital Investment	\$423 million
Net Back Price per annual gal	\$6.92

The net back price of \$6.92 was 3.2 times the then current sales price of corn ethanol.

Cellulose is a polymer of sugars that has a different structure than starch as shown in **Fig. 11**.

In starch, the CH<sub>2</sub>OH groups of the monomers are on the same side of 6-member ring. In cellulose, they are on the opposite side of the rings. This leads to cross linkage, which leads to dense packing of the polymer chains as shown in **Fig. 12**, making cellulose insoluble in water, and attack by enzymes to unzip the polymers and release the sugar monomers slow. Special, high cost enzymes are needed. Cellulose also incorporates pentose monomers in addition to glucose monomers. A cellulose pretreatment step is required ahead of fermentation. Pretreatment may involve treatment with strong or dilute acids, ammonia, or alkaline peroxides. Thus, the pretreatment step may be corrosive, requiring high cost materials of construction, such as stainless steel, instead of low-cost carbon steel. The chemicals used in the pretreatment step may convert the pentose monomers to furans, which may inhibit enzyme attack, further slowing the kinetics. Slow kinetics means large pretreatment vessels, further increasing the cost of the pretreatment step. Thus, the pretreatment step may add one third to the capital cost ahead of fermentation which currently makes cellulosic ethanol less economic than corn ethanol, which already struggles economically.

Fig 11. The difference between starch and cellulose

Fig 12. The difference between starch and cellulose packing structures

Plant biomass also includes lignin in addition to cellulose, which becomes a byproduct and lowers ethanol yield based on total biomass carbons. Byproduct lignin yield is high, and lignin becomes a nuisance byproduct (Note the estimated low 76% yield above).

Thus, while cellulose may be a cheaper feedstock than corn, total cost of production must be considered, including capital charge and operating costs. The higher cost of capital, lower yield, and lignin formation currently outweigh the cheaper feedstock cost.

Again, cost should not be a deterrent to the development of a technology that can help displace future fossil fuels with renewable fuels. However, cost has led to slow development and implementation. Continued research on cellulosic ethanol is justified at the moment while gasoline vehicles continue

to dominate. A breakthrough in better enzymes would help. However, a better solution is a move away from hydrocarbon vehicles.

Instead of spending money on high capital cost, high cost enzymes, and other operating costs to convert cellulose to ethanol, sequestration of the biomass may be a more effective way to remove biomass carbon from the Carbon Cycle. High yield crops, such as switchgrass, which can be grown where corn cannot, should be considered for this operation. Switchgrass has an average yield of 2.3 tons per acre, and yield can be as high as 6-7 tons per acre [48]. Switchgrass has been suggested as a renewable energy source that can be mixed with coal and burned to generate electricity. This would make the switchgrass carbons renewable. However, CO<sub>2</sub> from the burned switchgrass would still enter the atmosphere. A more effective way of removing CO<sub>2</sub> ALREADY in the atmosphere would be secure sequestration of the switchgrass biomass.

One issue may be how to pass the cost on to society of biomass sequestration. Psychologically, it is easier for the public to bear the cost of bioethanol, when they are getting something tangible to put in their gas tanks. Getting society to bear the cost of putting biomass into the ground forever is going to be more of a challenge. Perhaps the fairest way is to charge the cost of sequestration as a carbon tax on industries generating CO<sub>2</sub>.

6. Biodiesel

Biodiesel is produced by the transesterification of vegetables oils with methanol. The reaction is:

Economic production of methanol requires large plants to achieve economy of scale, and the ethanol is made from cheap natural gas from fracking [27]. Thus, the methanol comes from a fossil fuel. The reaction makes fatty acid methyl esters (FAME) having carbon numbers in the diesel boiling range. FAME has cetane and other properties that make it acceptable for blending into diesel. It is not used neat, and thus, the diesel pool will continue to rely on diesel from fossil fuels

Petroleum diesel is comprised of a more or less normal distribution of hydrocarbons from about C9 to C23, peaking around C16. Vegetable oils from different sources produce FAME having carbon number distributions as shown in **Table 1**. U.S. biodiesel uses primarily soybean oil. Rapeseed oil is the preferred feedstock in Europe. For the 2017/2018 season, about 30% of U.S. soybeans were used for biodiesel [28]. That is a huge diversion of crops to satisfy only about 3% of the U.S diesel pool. That is the reality! One issue for biodiesel is the production of about 11 parts of glycerin as a nuisance byproduct per 100 units of FAME.

Oil or fat	14:0	16:0	18:0	18:1	18:2	18:3	20:0	22:1

Note: 18:2 means a side chain of 18 carbons with 2 double bonds, etc.

## **7. Other Routes For Biomass to Fuel**

Some other routes for converting biomass to fuels are discussed in this section. Most are still in their infancy and at a scale that does not make a significant contribution to the 3600 MMtons/yr CO<sub>2</sub> removal needed to keep up with current generation.

What was the first use of biomass for fuel? The campfire. Now most developed countries use other fuels for home heating, such as natural gas, propane, or fuel oil. Why? Because gathering firewood is labor intensive. Not everyone has access to wood. Fireplaces are inefficient and create smoke and soot. This simple example illustrates that just because there is a solution to a problem, it may not necessarily be the best or most economical solution. As noted, economics should not prevent consideration of solutions for solving global warming. However, it can influence which technologies will dominate in a free marketplace.

Converting biomass to biofuels is inefficient due to parasitic energy loss. Cellulosic biomass to bioethanol will incur yield loss to CO<sub>2</sub> via the fermentation reaction, and yield loss to byproducts, such as lignin, and other challenges. Rather than spending capital and energy converting biomass to biofuels, simply burning the biomass to produce power may be a more cost-effective solution. Indeed, this is being commercialized now on a large scale.

The March, 2020 issue of National Geographic has an article titled “The End of Trash” [49]. The article describes an incinerator in Denmark that converts 534,600 tons of municipal waste a year to produce electricity for 30,000 homes and to heat 72,000. Thus, the carbon in this waste becomes renewable, and displaces FUTURE CO<sub>2</sub> from fossil fuels used to generate energy for this heating and electricity consumption. The burning of the waste generates CO<sub>2</sub>, albeit renewable CO<sub>2</sub>. From the standpoint of the carbon cycle, this material would have eventually decomposed and released its carbon back to the atmosphere, so the net gain is the displacement of fossil fuels. CO<sub>2</sub> from the

burning of waste still enters the atmosphere. There are also issues with feeding non-organics to furnaces.

This article describes and calls for other interesting steps that can or should be taken towards a sustainable economy. The need to reduce food waste, and the reuse of used clothing are examples. Wood chips are now being used as a replacement for coal in power plants [50-52]. This does replace FUTURE CO<sub>2</sub> produced from fossil fuels with a renewable fuel source. 1497 dry metric tonnes of wood chips were exported from the U.S in 2016, representing the equivalent of 2418 U.S. short tons of CO<sub>2</sub> [53]. However, some argue that these plants can have a number of draw backs including clearing U.S. forests for export, and low power plant efficiency. Numerous power plants based on wood chips or biomass have sprung up across the U.S. For an eye opening discussion of some of the issues surrounding them, see the movie by J. Gibbs and M. Moore [4]. Of course, like coal, wood chips can be gasified to form synthesis gas. But, as proposed here, perhaps it is better to remove that biomass from the Carbon Cycle and bury it securely.

Professor Huber's group at the University of Massachusetts developed fast pyrolysis of biomass as a process for converting biomass to a bio-oil that can be used as feedstock to produce fuels and chemicals [54]. In the lab, biomass was heated very rapidly using a Pt wire heating medium to produce the bio-oil. The reaction is over in seconds. The issue is how to do rapid heating and conversion on a commercial scale. Leave it to man's ingenuity. UOP called upon its knowledge of refinery Fluid catalytic cracking (FCC) to develop an analogous process, its Rapid Thermal Processing (RTP™) process [55]. A description of that process is provided below.

In a Refinery Fluid Catalytic Cracking (FCC) unit, ultrastable zeolite-Y (USY) catalyst is mixed with gas oil and sent up a tube (a riser reactor), where large molecules are cracked to smaller gasoline or diesel range molecules [56]. Reaction takes place at high temperature (over 500 C) and is highly endothermic. Thus, an ingenious way to heat the feed and catalyst was needed. Liquid feed is preheated by conventional feed/effluent heat exchange followed by supplemental heating in a furnace. The catalyst deactivates very quickly and is essentially dead after it exits the riser due to carbonaceous coke laydown. The coked catalyst is directed to a regenerator where it is fluidized by compressed air. The air burns the coke forming CO<sub>2</sub> in a highly exothermic reaction. This heats the regenerated catalyst to a temperature above its entrance temperature. When blended with preheated feed, the right temperature for reaction is achieved. Heat from the burning of coke reduces heat needed to preheat the gas oil feed. The heat balance between endothermic catalytic cracking and exothermic coke burn is critical to FCC unit design and operation.

In the UOP RTP™ process, the FCC catalyst is replaced by sand. Like FCC, the RTP™ process produces a lot of coke. Thus, like FCC there is a balance between the endothermic fast pyrolysis and regenerator. The bio-oil produced is full of oxygenates including acids, so it is very corrosive and unstable, requiring expensive materials of construction. The bio-oil must be hydrotreated to reduce oxygenates to be useful in downstream processes. UOP claims yield of bio-oil is high, but that means around 70%. Some gas is generated, but also some heavy oil, which is a nuisance byproduct. UOP has proposed using the oil as fuel for generating electricity. Heating value of the oil is only about half that of conventional No. 2 fuel oil. UOP working with partners has developed special burner tips. In the end, UOP claims the economics can compete favorably against No. 2 fuel oil.

Algae has been touted as having a high oil content that can be used to produce biodiesel. Exxon Mobil has partnered with Synthetic Genomics, Inc. (SGI) to produce an algae strain that has about 40wt% oil [57]. Algae is said to offer the following advantages. It can be grown on non-arable land. It is a non-food biomass source. One may envision integrated power plant/algae biodiesel plants that grow algae from CO<sub>2</sub> in power plant furnace exhaust. However, the process looks complex and expensive and scale-up to appreciable size appears to be a long way away. Also, while 40% oil content is high compared to the 18-19 wt% of oil in soybeans, what do you do with the balance of the algae after the oil is extracted?

In order to pull more carbon from the atmosphere or flue gas, it might be better to grow algae, slurry it with water, and sequester the whole of the algae biomass by pumping it into spent oil wells or other reservoirs.

## **8. CO<sub>2</sub> Sequestration Technologies**

CO<sub>2</sub> sequestration can remove CO<sub>2</sub> from industrial furnaces, including furnaces used in the generation of electricity from coal or natural gas. Thus, it can target CO<sub>2</sub> generation from the industrial and electric power sectors, which together account for over 50% of CO<sub>2</sub> generation. This is substantial, but not a complete solution to the CO<sub>2</sub> problem.

The message for CO<sub>2</sub> sequestration is: We know how to do it, with proven technologies, some of which have been practiced for close to 100 years. It is going to cost money, and scale-up to the size needed is going to be an issue.

Three ways have been proposed for CO<sub>2</sub> sequestration, High level bullet points for some of the advantages and disadvantages are provide below and will be discussed in more detail.

- **Direct CO<sub>2</sub> Capture from air**
  - Dilute (400 ppmv CO<sub>2</sub>)
  - Must move massive quantities of air
  - Can remove CO<sub>2</sub> ALREADY in the air
- **Post-Combustion CO<sub>2</sub> Capture**
  - Fuel burned and CO<sub>2</sub> removed from furnace stack gas
  - CO<sub>2</sub> still dilute (5-10 vol% depending on fuel source and composition) due to nitrogen from combustion air
  - Flue gas near atmospheric pressure, and must be blown (compressed) through absorber or adsorption bed
  - Can be applied to flue gas from natural gas or coal-fired power plants making both “clean”
  - Appropriate to sequester CO<sub>2</sub> from massive EXISTING furnace installed base
  - Can be retrofitted to existing furnaces
- **Pre-Combustion CO<sub>2</sub> Capture**
  - Requires new-build integrated power plants
  - For natural gas fuel, basically modification of a steam reforming H<sub>2</sub> plant which has been practiced for nearly 100 years

- Steam reforming of natural gas or partial oxidation of coal to form syn gas ( $\text{CO} + \text{H}_2$ )
- Water-gas shift to produce  $\text{CO}_2$  and more  $\text{H}_2$ :  $\text{CO} + \text{H}_2\text{O} = \text{CO}_2 + \text{H}_2$
- $\text{CO}_2$  removed by absorption or adsorption, before producing a clean burning  $\text{H}_2$  fuel (pre-combustion)
- In combined cycle power plant, exothermic reactions produce steam to turn turbines to generate electricity
- Hydrogen can be burned to generate more steam to make more electricity or exported for refinery or chemical use or other fuel use
- The so-called “Hydrogen Economy”

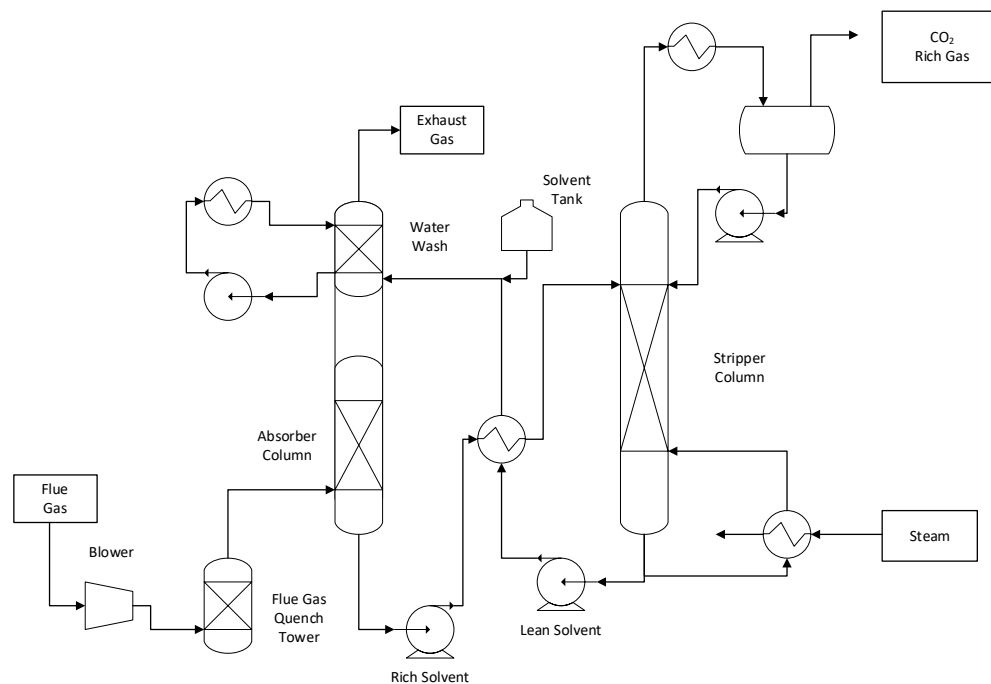

All CO<sub>2</sub> sequestration technologies will face the issue of what to do with the CO<sub>2</sub> product, especially at the scale needed to keep up with the new introduction of CO<sub>2</sub> into the atmosphere from continued use of fossil fuels (36 billion tons/yr). Permanent disposal of sequestered CO<sub>2</sub> is discussed below.

### 8.1 Direct CO<sub>2</sub> Capture From Air

There are companies trying to commercialize pulling CO<sub>2</sub> directly from air [29]. The obvious issue is the need to move massive quantities of air through an absorber or adsorber to recover even a trivial amount of CO<sub>2</sub>. In my opinion, this is simply not practical.

## 8.2 Post-Combustion CO<sub>2</sub> Capture

A process schematic for post-combustion CO<sub>2</sub> capture is shown in **Fig. 13**.

**Fig. 13** The post-combustion CO<sub>2</sub> capture process

The heart of the process is adsorption into a solvent, typically an amine, followed by stripping the CO<sub>2</sub> from the amine via distillation. Typical solvents include MEA (monoethylamine) and DEA (diethylamine), which requires less energy to strip the amine than MEA.

This technology can be retrofitted on the massive installed base of existing furnaces of power plants, and refinery and chemical processes. Thus, it should be an essential part of a comprehensive attack on global warming from CO<sub>2</sub>.

In Post-Combustion capture, flue gas is near atmospheric pressure and must be blown through an absorber or adsorption bed. This requires a blower (low pressure compressor) and its associated capital and operating cost. One issue for post-combustion CO<sub>2</sub> capture is that the CO<sub>2</sub> is still dilute due to nitrogen from the air used to combust the fuel. The technology can be retrofitted to either natural gas- or coal-fired power plants. The concentration of CO<sub>2</sub> in the flue gas can be calculated from the composition of the fuel. For methane combustion, the reaction is:

Since combustion air is 79 mol% N<sub>2</sub>, it dilutes the CO<sub>2</sub> product. Also, furnaces are operated with a small amount of excess air.

CO<sub>2</sub> concentration would vary from about 5 mol% for natural gas to 10 mol% for coal due to its higher C:H ratio, which depends on the grade of coal.

The flue gas from the furnaces is hot. Absorption is endothermic, and thus is favored by lower temperature. The flue gas must first be cooled in a cooling or quench tower. This tower also knocks out some of the water of combustion down to its vapor pressure at the temperature at which this tower operates. A water pump around may be used as shown. The absorber itself must be cooled by cooling water. The absorber would typically have two sections as shown: a lower section where a rich amine solution is sent to the top of the section and this section acts as a true stripper. The upper section would include a water pump around with further cooling to reduce the concentration of amine in the product gas stripped of CO<sub>2</sub>.

The rich amine solution (rich in CO<sub>2</sub> but diluted by remaining water from combustion) exits the bottom of the tower is pumped through a preheat feed/effluent exchanger to the CO<sub>2</sub> stripping tower. CO<sub>2</sub> product is taken overhead, compressed to liquify, and sent to storage. The lean amine solution stripped of CO<sub>2</sub> is recycled back to the absorber.

The air to large industrial furnaces is controlled by dampers. Large furnaces typically run at 2-4% excess oxygen (and of course 79/21 time more nitrogen). It is most economical to run at a low excess oxygen since heat is absorbed by the excess oxygen and excess nitrogen and is wasted by venting the hot flue gas. However, it cannot run too low, because that can starve the flame, causing soot formation (black stack gas exiting the furnace) and could cause safety issues during upsets that would extinguish the flame with fuel still fed to the furnace. Oxygen can cause degradation of the amine absorbent or solid adsorbent. Solid adsorbents are being investigated as an alternative to absorption to save energy from the amine stripping step. This technology works and removal of acid gases like CO<sub>2</sub> and H<sub>2</sub>S from refinery streams has been practiced for about 100 years. Application to recover CO<sub>2</sub> from power plant flue gas is in the demonstration stage. A photo of Alabama Power's Plant Barry demonstration unit is shown in **Fig. 14** [30-32].

**Fig. 14** Alabama Power Plant Barry CO<sub>2</sub> Capture Demonstration Unit Showing the Scale [30-32].

This photo shows the issue: scale-up. This demo unit pulls CO<sub>2</sub> from the flue gas of the equivalent of 25 MW of power generation. The plant occupies a plot space of 90 m by 45 m. A large power plant may be 1000 MW, and thus, a CO<sub>2</sub> capture plant to treat the entire power plant effluent will be massive. Production of amine is energy intensive, and a massive amount of amine would be needed to treat significant amounts of flue gas. Thus, scale up is an issue. That is the reality!

The technology has now been scaled up to semi-commercial scale. The Petra Nova power plant began commercial sequestration from flue gas of the equivalent of 240 MW (37% of the total plant emissions) in January 2017 [33]. It is a start, but there is a long way to go. That is reality!

### **8.3 Pre-Combustion CO<sub>2</sub> Capture**

Pre-Combustion CO<sub>2</sub> capture involves steam reforming or partial combustion of a fuel to form synthesis gas (a mixture of CO and H<sub>2</sub>). In principal, any fuel containing carbon can be converted to synthesis gas.

For high H:C fuels, CO is converted by reacting with water to form CO<sub>2</sub> and more H<sub>2</sub> via the water gas shift reaction.

Steam reforming is preferred for natural gas. The reaction for methane is:

For coal, partial oxidation is preferred:

The steam reforming reaction forms some hydrogen directly.

Both steam reforming and partial oxidation reactions are followed by the water-gas shift reaction to form more hydrogen and CO<sub>2</sub>:

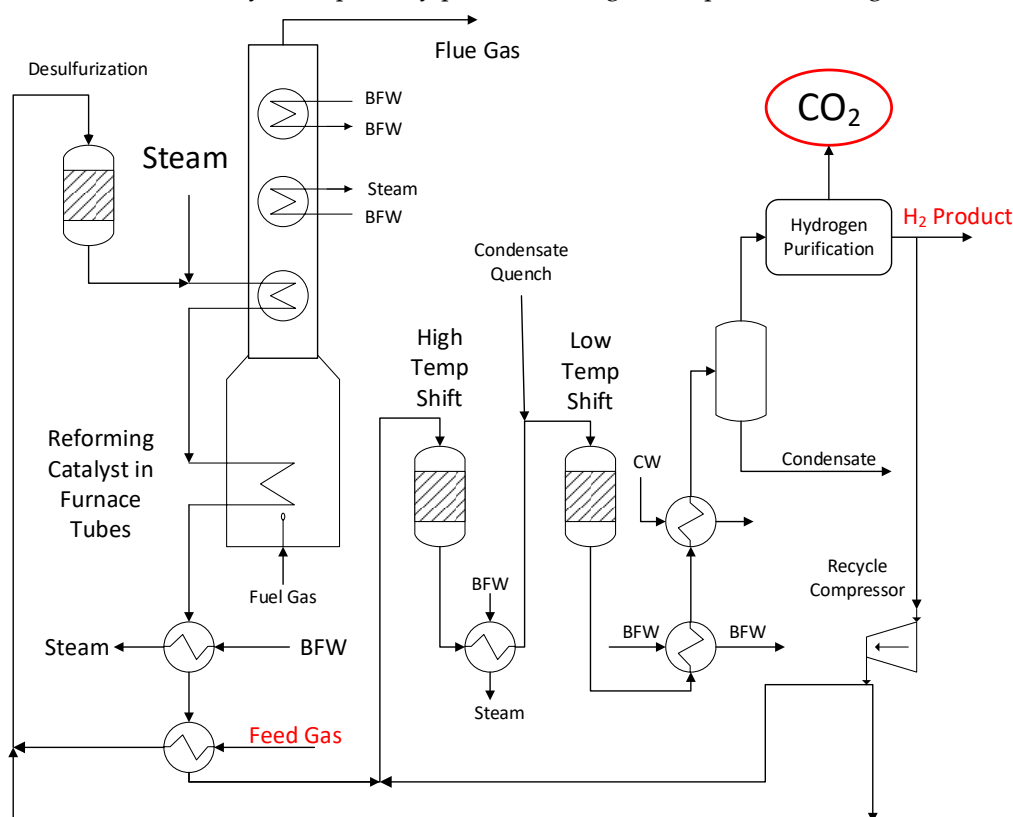

The CO<sub>2</sub> is captured by absorption or adsorption. One advantage for pre-combustion capture compared to post-combustion is that the water-gas shift reactor effluent is at moderate pressure (10-20 barg). Thus, it does not need a separate blower to move it through an absorber or adsorber, and adsorption processes that used pressure swing are possible.

Steam reforming of methane is the technology used in hydrogen plants, a technology that has been used for nearly 100 years to produce supplemental hydrogen for refineries and chemical processes. A schematic of a steam reforming hydrogen plant is provided in **Fig. 15**.

Feed gas is preheated and pretreated to remove sulfur. For natural gas with low levels of sulfur, sulfur may be removed by passage through a bed of zinc oxide where the sulfur is converted to zinc sulfate. Feed gases with higher amounts of sulfur (coal, for example) require a hydrotreater.

The pretreated gas is mixed with steam (and some recycled hydrogen product) and reformed over a catalyst at high temperature. For typical smaller size hydrogen plants, the reforming “reactor” is catalyst packed right into furnace tubes. The feed is first preheated by heat exchange with hot flue gas. Heat is recovered from the hot flue gas by generating steam. The hot effluent from the steam reforming reactor is cooled and passed to water-gas shift reactors. Equilibrium conversion to  $\text{CO}_2$  and  $\text{H}_2$  in the water-gas shift reactors is favored by low temperature. Water-gas shift is usually done in two steps. A first high temperature shift reactor is used to provide faster reaction kinetics. A second low temperature shift reactor is used to favor higher equilibrium conversion.

$\text{CO}_2$  is removed from the shift reactors effluent by either absorption in an amine solution, followed by stripping of the  $\text{CO}_2$  product by distillation, which requires steam, or by adsorption on a molecular sieve bed followed by desorption by pressure swing or temperature swing.

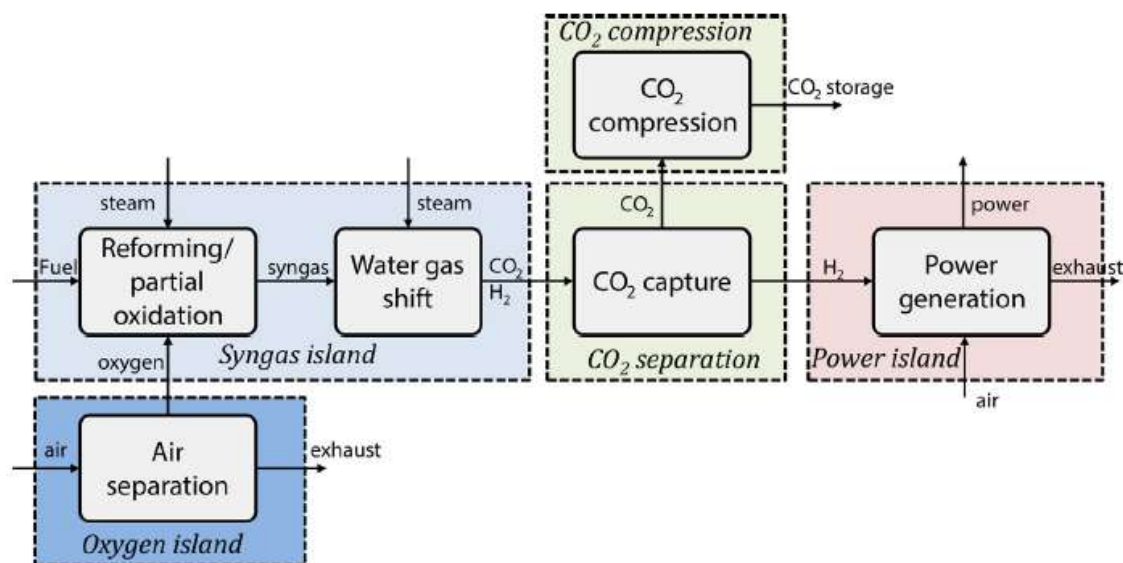

**Fig. 15.** Process Flow Diagram for a Hydrogen Plant

BFW = Boiler Feed Water; CW = Cooling Water

The hydrogen atoms in the methane are converted to water. The water is mainly removed by cooling and separation in a condensate drum.  $\text{CO}_2$  is separated in the hydrogen purification section, by absorption, as shown in Fig. 13, or by adsorption in a Pressure Swing Adsorption (PSA) unit.

Note that steam is generated in multiple places in the process. That steam can be used to turn turbines to generate electricity in a combined cycle power plant.  $\text{CO}_2$  is removed from the water-gas shift reactor effluent, compressed to liquify, and sent to storage. Thus, a clean high purity hydrogen product is produced. In a combined cycle power plant, the hydrogen (the Pre-Combustion fuel product) can be burned to produce more steam and more power, or it can be exported for use in a refinery or chemical plant or elsewhere (the basis for a hydrogen economy). Partial oxidation of coal or other high carbon content fuels is usually done in open flame reactors, preferably using pure oxygen, because air would dilute the synthesis gas by the nitrogen. Thus, for coal, the Oxy-Fuel Pre-Combustion process shown in Fig. 16 may be preferred [34].

**Fig. 16.** Oxy-Fuel Pre-Combustion Combined Cycle Power Plant

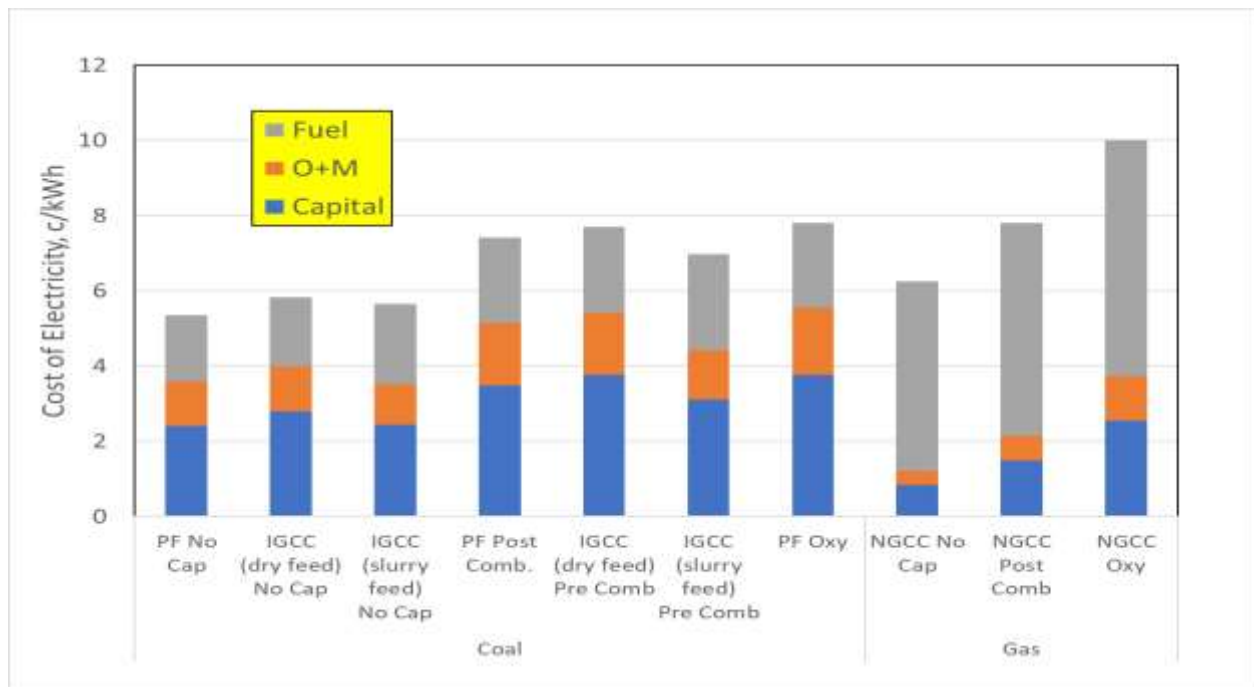

Source: Jansen, et al. [34]

One obvious drawback is the need for an air separation plant to generate the pure oxygen. One can envision an Oxy-Fuel Pre-Combustion plant, where the nitrogen from the air separation plant is used with the hydrogen product to produce ammonia.

In summary, we know how to do  $\text{CO}_2$  capture via Pre-Combustion or Post-Combustion. It uses proven technology. It works. It will cost money. How much money?

The efficiency of a power plant can be defined as the amount of electricity generated per unit of fuel to the process.  $\text{CO}_2$  capture does not come free. The energy required by  $\text{CO}_2$  capture is parasitic energy, and the extra fuel required to do the  $\text{CO}_2$  stripping, run pumps, cooling tower fans, and compressors has the effect of reducing power plant efficiency, which is reflected in an increase in the net back price for the electricity. This increase in net back price is often referred to as the “Cost of  $\text{CO}_2$  Capture.”

The IEA web site has a wealth of information on carbon capture [35-36]. It is highly recommended for those interested in the subject. In the 2007 report, the cost of electricity is estimated for both coal and natural gas with and without various power plant configurations. Projected cost for electricity with carbon capture are shown in Fig. 17.

**Fig.17.** Projected Electricity Price With and Without CO<sub>2</sub> Capture (Various Plant Configurations)

Source: (IEA, 2017) All Rights Reserved. [36]

The relative increase in electricity cost was projected to be 23-40% higher for coal and 25-60% higher for natural gas based on then current European pricing and depending on power plant technology (excluding the cost for CO<sub>2</sub> transportation and cost for underground storage. The percentage increase in the U.S. would be higher due to cheap natural gas feedstock cost. Cost is higher, but not abhorrent. This is reality! If we want to solve the CO<sub>2</sub> problem, this is what it is going to take. Again, CO<sub>2</sub> sequestration should be considered a necessary tool to reduce CO<sub>2</sub> emissions from FUTURE continued burning of fossil fuels. Its implementation would have a huge impact. However, it alone cannot get the world to Net Zero CO<sub>2</sub>.

#### 8.4 What to Do With the Captured CO<sub>2</sub>

Now that CO<sub>2</sub> has been captured and liquified, this product needs a home. The CO<sub>2</sub> can be compressed, liquified and transported to its final destination. CO<sub>2</sub> transportation by pipeline is proven technology. The first increments of captured CO<sub>2</sub> have commercial value for the soft drink and other industries, and for use in tertiary oil recovery. **Fig. 18** provides IEA projected cost for CO<sub>2</sub> on-shore storage as a function of cumulative CO<sub>2</sub> captured [35]. Cost is negative for the first 6-7 MMtons/yr CO<sub>2</sub> captured due to its value to the commercial markets (beverages, tertiary oil recovery, etc.) Beyond that there is a positive cost to transport and sequester CO<sub>2</sub> underground. Cost remains flat at about \$12-14 per MMton/yr up to about 28 MM tons, and then rises very rapidly. Thus, it is not practical to get it all.

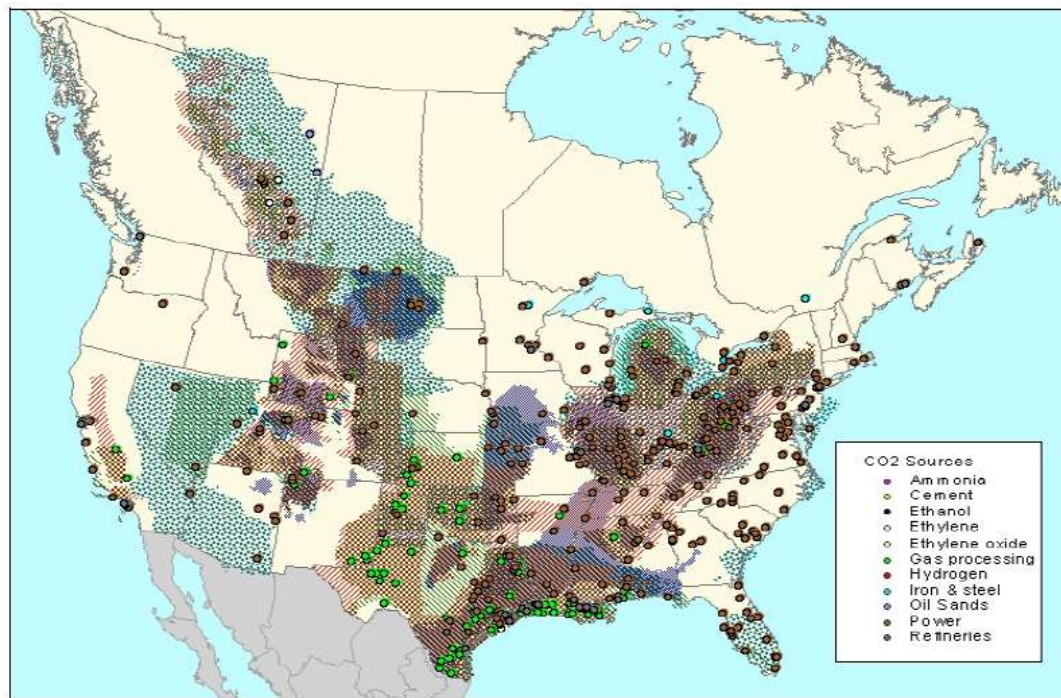

**Fig. 18.** Projected Cost of CO<sub>2</sub> Storage as a Function of Cumulative Amount Captured.

Source: (IEA, 2017). All Rights Reserved. [36]

The next issue is where to put all of the sequestered CO<sub>2</sub>. It has been proposed to store it underground in spent oil wells, or in geological formations. **Fig. 19** shows that there are potential storage locations near the 500 largest point sources [35]. Overlap of location of large point sources and potential locations for storage is good, indicating that liquified CO<sub>2</sub> might not have to be transported very far. Note that some bioethanol plants make the list of 500 largest point sources. Technology for capping underground oil wells is well known. The challenge is how to utilize underground caverns to store a volatile gas at atmospheric pressure. (There may be a better use for these locations, such as biomass sequestration.)

One novel thought about sequestering the CO<sub>2</sub> is to react it with lime (a mixture of calcium oxides and hydroxides) to form calcium carbonate in a fluid bed reactor [59-60]. The issue is moved to where to get all the lime needed and where to dispose of the calcium carbonate. Also, the kinetics of reacting gaseous CO<sub>2</sub> with solid lime may be very slow.

**Fig. 19.** Overlap of 500 Largest Point Sources with Potential Locations for Storage

### **8.5 Sequestration of Tree Leaves and Municipal and Yard Waste**

As noted earlier, fossil fuels and CO<sub>2</sub> sequestration will prevent FUTURE CO<sub>2</sub> from fossil fuels entering the atmosphere. However, as we have seen doing it on a scale needed to meet current and future energy demands is daunting. Furthermore, CO<sub>2</sub> sequestration is not a complete solution, so other solutions are needed.

Per an understanding of the Carbon Cycle, the only way to remove CO<sub>2</sub> ALREADY in the atmosphere is to grow biomass and remove that biomass from the Carbon Cycle. We have already argued that growing corn and algae and sequestering the total mass would have a bigger impact than inefficiently converting only a portion of that biomass (corn kernels) to fossil fuels. That would pull some CO<sub>2</sub> ALREADY in the atmosphere. However, as shown above it is not enough. Sequestering all of the biomass in the 40% of the U.S. corn crop now devoted to bioethanol would only remove 406.9 MM metric tonnes of CO<sub>2</sub> per year compared to the 36 billion tonnes generated. Something else is needed to achieve Net Zero CO<sub>2</sub> to the atmosphere.

The answer is secure burial of biomass from other sources, including municipal and yard waste, and biomass generated in forests (tree leaves and wood). By secure burial, we mean permanent burial with provisions taken to prevent decomposition and release of the CO<sub>2</sub> to the atmosphere. Some thoughts on how to achieve secure sequestration with minimal or no CO<sub>2</sub> to the atmosphere are provided in the next section.

Permanent sequestration of municipal and yard waste in permanent landfills would remove that carbon from the Carbon Cycle and would remove CO<sub>2</sub> ALREADY in the atmosphere that would feed the growth of the organic materials in those waste sources. In addition, it would remove CO<sub>2</sub> going

to the atmosphere from refinery and petrochemical processes used to produce plastics, if plastics are included in the waste to be buried. The systems are in place to collect yard and municipal waste in most large cities in the U.S., and elsewhere in the world, so part of the cost is already sunk.

Some municipal waste is now burned to generate renewable power [49]. One issue for that application is that even after separation of recyclables, average municipal waste still contains about 20% non-organics (glass, metal, etc.) that must be separated before the organics can be burned. Secure burial to sequester all of the waste would not require this stringent and costly separation.

How big of a difference could secure sequestration of municipal and yard waste make? The U.S. EPA keeps statistics on municipal and yard waste generated, and how much is ultimately landfilled [38]. In 2017, the total amount of U.S. municipal and yard waste generated was 267.8 MM short tons. Some is separated and recycled, some is currently burned to generate renewable power, leaving the amount landfilled at 139.6 MM tons, with composition provided in **Fig. 20**. The organic component was 112.5 MM tons. That corresponds to 149.6 MM metric tonnes of CO<sub>2</sub> if allowed to completely decompose. This compares to the 6480 MM tons per year CO<sub>2</sub> generated in the U.S. and is far short of the 36000 MMtons/yr CO<sub>2</sub> currently being generated worldwide. Participation by other countries would help, but clearly not enough to solve our daunting CO<sub>2</sub> problem.

We need to turn to our other resources for pulling CO<sub>2</sub> from the atmosphere: trees, both tree leaves and wood. The USDA has provided allometric equations for urban tree growth parameters for many species and at numerous locations in the U.S. [39]. The growth equations have been programmed into EXCEL files that are provided in Section SI.2. Dry leaf biomass is calculated for most species and regions where data is available.

**Fig. 20.** U.S. 2017 Municipal and Yard Waste Landfilled  
Source: (EPA, 2020) [38].

As shown in **Fig. 21**, Dry leaf biomass can be over 100 kg/yr for some of the maples and over 400 kg/yr for some of the oaks depending on location and age. Mature tree wood weights can be several metric tonnes per tree, as shown in **Fig. 22**. Leaves currently fall to the ground and decompose each year.

Assume a conservative average of 50 kg/yr dry weight of leaves per tree. If forests were managed, the leaves gathered and permanently securely buried, this would be the equivalent of over (50 kg/yr dry wgt)\*(44.01 gm CO<sub>2</sub>/30.03 gm CH<sub>2</sub>O) = 73 kg/yr CO<sub>2</sub> removed from the atmosphere per tree every year.

According to the latest estimate, there are over 3 trillion trees in the world [40]. At 73 kg/yr-tree CO<sub>2</sub> equivalent per tree that is the potential to remove 219 billion metric tonnes CO<sub>2</sub>, compared to 36 billion tonnes CO<sub>2</sub> generated each year. Thus, theoretically sequestering tree leaves could provide a complete solution to our CO<sub>2</sub> fossil fuel problem. The potential is enormous. Of course, not all trees are deciduous, or readily accessible. Also, the problem is still daunting. Leaves from about 16% of the world's tree population would be needed for a complete solution. Removal and secure burial of tree wood would help. Harvesting tree wood as a means of CO<sub>2</sub> sequestration would be labor intensive and expensive. Furthermore, it is not needed. Harvesting the leaves would suffice. Also, harvesting leaves alone would not disrupt the forest itself, and leaves are renewed every year. It is best to leave the wood for its current uses (construction, furniture, etc.) Managing new forest plantings should be considered with access provided for leaf collection.

The amount of space needed to bury all of the leaves is daunting when the weight of leaves required is compared to the current amount of municipal waste. However, this is what would be needed for a complete solution to get the world to Net Zero CO<sub>2</sub> emissions. The amount required would of course

be reduced by increased energy conservation, new solar and wind energy, the move of the transportation sector away from fossil fuels, and new CO<sub>2</sub> sequestration from large point sources.

Tree population is not distributed evenly around the world or even around the U.S. The U.S. has 228 billion trees, Brazil has 301 billion, Canada has 318 billion, and China has only 139 billion [41]. About 50% of Russian land area is covered by forests. U.S. trees are concentrated in the Northwest, East Coast, Southeast, and West Coast. Of course, sequestering leaves from all of these trees poses logistic problems. However, as noted above only a fraction is needed, especially if combined with other solutions.

The bottom line is there are solutions that can keep up with world CO<sub>2</sub> generation. Some will not be easy or inexpensive, but there is hope. Everything is needed: energy conservation, the move to electric vehicles charged by power plants with CO<sub>2</sub> sequestration, secure burial of municipal and yard waste, leaf sequestration, solar, wind, etc.

## 8.6 Thoughts on How to Achieve Secure Permanent Sequestration

Permanent sequestration of municipal waste and tree leaves will require rethinking how landfills are designed. Currently, landfills are designed to encourage some degradation of the waste. Permanent sequestration requires discouraging waste degradation [37,61].

Currently, yard waste is collected, and a portion is used to produce mulch, but it eventually decomposes and releases its carbon back to the atmosphere. Some municipal waste is now burned to generate renewable power [49]. One issue for that application is that even after separation of recyclables, average municipal waste still contains about 20% non-organics (glass, metal, etc.) that must be separated before the organics can be burned. Secure burial to sequester all of the waste would not require this stringent and costly separation.

Municipal waste is buried in landfills, where it gradually decomposes. It undergoes a combination of aerobic and anaerobic decomposition to produce a biogas. Modern landfills undergo five distinct stages.

### Initial adjustment (Phase I)

As the waste is placed in the landfill, the void spaces contain high volumes of molecular oxygen (O<sub>2</sub>), and the waste starts to undergo aerobic decomposition forming CO<sub>2</sub>. As waste is added and compacted, the O<sub>2</sub> content of the landfill decreases, microbial colonies increase, and waste density increases.

### Transition (Phase II)

The O<sub>2</sub> is rapidly exhausted by the existing microbial populations. The decreasing O<sub>2</sub> leads to less aerobic decomposition and more anaerobic decomposition.

### Acid formation (Phase III)

Hydrolysis of the biodegradable fraction of the solid waste begins in the acid formation phase, which leads to rapid accumulation of volatile fatty acids (VFAs) in the leachate. The increased organic acid content decreases the leachate pH from approximately 7.5 to 5.6.

During this phase, the decomposition intermediate compounds like the VFAs contribute much chemical oxygen demand (COD). Long chain volatile organic acids (VOAs) are converted to acetic acid ( $C_2H_4O_2$ ),  $CO_2$ , and hydrogen gas ( $H_2$ ). High concentrations of VFAs increase both the biochemical oxygen demand (BOD) and VOA concentrations, which initiates  $H_2$  production by fermentative bacteria, which stimulates the growth of  $H_2$ -oxidizing bacteria. The  $H_2$  generation phase is relatively short because it is complete by the end of the acid formation phase. The increase in the biomass of acidogenic bacteria increases the amount of degradation of the waste material and consumes nutrients.

#### **Methane fermentation (Phase IV)**

The acid formation phase intermediary products (e.g. acetic, propionic, and butyric acids) are converted to  $CH_4$  and  $CO_2$  by methanogenic microorganisms. As VFAs are metabolized by the methanogens, the landfill water pH returns to neutrality. The leachate's organic strength, expressed as oxygen demand, decreases at a rapid rate with increases in  $CH_4$  and  $CO_2$  gas production. This is the longest decomposition phase.

#### **Final maturation and stabilization (Phase V)**

The rate of microbiological activity slows during the last phase of waste decomposition as the supply of nutrients limits the chemical reactions, e.g. as bioavailable phosphorus becomes increasingly scarce.  $CH_4$  production almost completely disappears, with  $O_2$  and oxidized species gradually reappear in the gas wells as  $O_2$  permeates downwardly from the troposphere. This transforms the oxidation–reduction potential (ORP) in the leachate toward oxidative processes. The residual organic materials may incrementally be converted to the gas phase, and as organic matter is composted; i.e. the organic matter is converted to humic-like compounds.

The anaerobic decomposition phase produces a biogas. On average, about half of the volumetric concentration of landfill gas is methane and slightly less than half is  $CO_2$ . The gas also contains about 5% molecular nitrogen ( $N_2$ ), less than 1% hydrogen sulfide ( $H_2S$ ), and a low concentration of non-methane organic compounds (NMOC), about 2700 ppmv [37]. Methane is a more powerful greenhouse gas than  $CO_2$ .

Landfills are now designed with underground collection systems, and the gas is typically routed to flares, and burned. Thus, the carbon in the gas is converted to  $CO_2$  which goes back to the atmosphere. Some landfills now route the gas to boilers for power generation (renewable power generation), or other uses.

Permanent sequestration of municipal and yard waste in permanent landfills would remove that carbon from the Carbon Cycle and would remove  $CO_2$  ALREADY in the atmosphere that would feed the growth of the organic materials in those waste sources. In addition, it would remove  $CO_2$  going to the atmosphere from refinery and petrochemical processes used to produce plastics, if plastics are included in the waste to be buried. The systems are in place to collect yard and municipal waste in most large cities in the U.S., and elsewhere in the world, so part of the cost is already sunk.

Some municipal waste is now burned to generate renewable power [49]. One issue for that application is that even after separation of recyclables, average municipal waste still contains about 20% non-organics (glass, metal, etc.) that must be separated before the organics can be burned. Secure burial to sequester all of the waste would not require this stringent and costly separation.

How can landfills be redesigned to minimize or eliminate biomass degradation? Phase I degradation could be minimized by minimizing the landfill working volume as material is moved to the non-working volume which is moving towards later phases. The working volume may be covered by tarps at night or covered by foam. This is already being done in some landfills.

A simplified equation for anaerobic degradation is:

The reaction requires water. Thus, the key to reducing or eliminating anaerobic degradation is to keep water out, i.e. to seal the landfill as it moves beyond Phase I.

Municipal waste used to be accumulated in open piles. Modern landfills with daily, intermediate, and final covers only began in the 1940s and accelerated in the 1960s and 1970s. None of the modern landfills have gone through their full life cycle, which can take hundreds to thousands of years. The evidence is huge mounds that are left by modern landfills that have had their final earthen caps installed and then abandoned for new sites. Can secure permanent sequestration really be achieved? Yes it can. The model for it is the story of how coal and oil were formed. Can some leakage be tolerated during the five stages? Yes. It will increase the amount of material that needs to be sequestered to compensate for these losses. Biogas can be collected and burned to generate renewable power and displace fossil fuels as is currently done at many landfill sites.

Thus, we envision secure permanent landfills that are small modifications of current landfills. These landfills may be located near the source of leaf biomass to minimize transportation cost.

## **9. Conclusions**

Carbon dioxide from fossil fuels is the main culprit of Global Warming. The problem is massive. 36 billion tons of CO<sub>2</sub> are being released into the atmosphere each year. Finding a solution requires an understanding of where energy is produced and consumed and a proper understanding of the Carbon Cycle. While renewable energy is growing rapidly, it remains a very small part of overall energy. Other solutions are needed.

Bioethanol and biodiesel remain a small part of energy for transportation, which itself is less than 30% of overall energy consumed. Corn ethanol is traced through its Carbon Cycle. Biofuels would at best be sustainable, but are not, when energy for their production, and the stoichiometry of the fermentation reaction are considered. Two of the six carbons of glucose are converted to CO<sub>2</sub>, which most facilities release to the atmosphere before any useful work is done in an engine. Cellulosic ethanol promises cheap feedstock, but still faces a number of technical and economic challenges. This has slowed implementation. Only about 15 MM gallons were produced in 2018 compared to 16,868 MM gal of corn ethanol. That is the reality!

CO<sub>2</sub> sequestration targets CO<sub>2</sub> produced in large industrial furnaces, including those used to generate electric power. Industrial and power plant furnaces account for about half of CO<sub>2</sub> generated. This is significant, but CO<sub>2</sub> sequestration will not be a complete solution. The message is: We know how to do it, using variations of technologies that have been used for over 100 years. It is just going to cost money and scaleup is a major issue. Post-combustion capture can be retrofitted to the massive installed base of industrial furnaces, and thus, must be an essential part of solving the CO<sub>2</sub> problem.

Pre-combustion capture is a variation of a hydrogen plant, which produces a clean burning hydrogen product that can be burned in a combined cycle power plant to generate more electricity or exported for use in a refinery, chemical plant, or even for residential use (a hydrogen economy). Natural gas can be steam reformed, and coal can undergo partial oxidation. With CO<sub>2</sub> sequestration, both natural gas and coal can become CO<sub>2</sub>-free fuels. The issue is that to date, few commercial-scale sequestration projects have been brought forward.

Biofuels and carbon dioxide sequestration can displace FUTURE CO<sub>2</sub> from continued use of fossil fuels. The only way to reduce CO<sub>2</sub> ALREADY in the atmosphere is to permanently sequester biomass. Rather than spending capital and energy to convert biomass to biofuels, permanent sequestration of biomass CARBON from tree leaves, crops, and municipal and yard waste is proposed. Theoretically, sequestration of only a fraction of the world's tree leaves can bring the world to Net Zero CO<sub>2</sub> and without disruption of the underlying forests. Thoughts are put forth on how to achieve secure permanent biomass sequestration.

## **10. Acknowledgements**

Amelse holds a Ph.D. in Chemical Engineering (1980) from Northwestern University. He retired in 2017 after 35 years of R&D at the Amoco Chemical Company (now BP Amoco Chemical Company Petrochemicals Technology, Naperville, IL USA), working mainly on paraxylene catalyst and process technology. He joined CICECO, Aveiro Institute of Materials, Department of Chemistry, University of Aveiro as Invited Principal Investigator to continue collaborating with Dr. Luis Mafra on the characterization of molecular sieve catalysts via Solid State NMR, work started while at BP. He also developed and taught a course on Petroleum Refining and Petrochemicals. He will begin a new 3-year year appointment with the Chemistry Department as Invited Associated Professor on August 1, 2020. This manuscript was developed between assignments with the university as an independent contributor.

**Conflicts of Interest:** The author declares no conflict of interest.
